As soon as the patient's condition permits, ambulation should begin. In addition to reducing the risk for contractures, deconditioning and deep venous thromboses, early gait training maintains balance, lower extremity ROM, strength, and endurance. Physical therapists use a tilt table to perform graduated upright positioning. Literature indicates that muscles of the lower extremities, particularly the gastrocnemius and quadriceps, are the first muscles to lose strength with bed rest. These same muscles experience a greater proportional loss of muscular torque when compared to other skeletal muscles (36,37).

The physical therapist can initiate gait training and determine appropriate assistive devices; however, physical therapy sessions should not be the only time the patient walks. Nurses, family, and others can learn how to assist and provide needed guarding during walking. Walking reduces the effects of bed rest and improves aerobic conditioning.

Many consider new autografts to the lower extremities a contraindication to ambulation. Typically, ambulation is not initiated until the surgeon is confident that the graft will tolerate a dependent position. At 5 to 7 days after grafting, patients are instructed to begin lower extremity-dependent positioning. Dangling the lower extremities is a preambulation exercise that helps determine if the graft tolerates the dependent position. The application of elastic wraps or other elastic devices are used to minimize venous pooling and decrease the risk of graft loss. The typical protocol for dangling begins for 5 minutes two to three times per day. If inspection of the graft after dangling shows no signs of intolerance, the duration is progressively increased. Once the graft shows tolerance for dependency, ambulation is initiated. Supportive dressings such as ace wraps are often employed. Like dangling, the time spent walking is methodically increased as the graft tolerates.

Gait deviations are common after burn injury. Some are transient while others persist. Early correction of abnormal stance and gait reduces the risk that the deviation will be long-standing. Deviations result from pain, location of injury, deconditioning, weakness, contractures, and sensory and central nervous system dysfunction. Gait devices are commonly used to protect injured areas, reduce pain, or assist with weight bearing. Devices are also employed to correct or prevent poor posture or gait deviations secondary to injury to the trunk or other areas.

During times that the patient is unable to ambulate, wheelchairs provide mobility and are easily adapted to the patient's specific needs. Adaptations include attaching splints or wedges to elevate the arm or adding lower-extremity positioning devices.

## SURGICAL RECONSTRUCTION

The surgical goal is to minimize surgery and maximize results. If multiple areas are involved, an overall plan and timetable are

developed that prioritize the fewest number of surgeries with the maximal functional benefit to the patient.

The timing of surgical release of a contracture varies. Some surgeons believe that surgery should wait 6 to 12 months after injury. However, there is limited evidence to support this recommendation. Other literature supports early intervention (38–40). There is evidence that early release does not worsen outcome, and surgery is indicated with the development of secondary deformities (41). Tendon and ligament injury impacts the completeness of the release that can be performed. Age, severity of the deformity, and time since injury impact surgical outcome (39,42).

Many reconstructive procedures are utilized in the burn-injured patient. Listed in the order of complexity are Z-plasty, skin graft, local skin flaps, local muscle flaps, fasciocutaneous flaps, free flaps, and cross limb flaps (38).

Simple excision is indicated for scars that are limited in size and location. Z-plasties are employed to limit or correct joint contractures caused by hypertrophic scarring. Contractures of soft tissue that disrupts appearance or tissue flexibility are also treated with Z-plasty. For example, this technique is employed to correct hypertrophic scarring over the chin that prevents adequate mouth closure (43). Release and skin grafting typically involves a fish-mouth incision and graft placement. Scar pressure therapy and silicone application are often combined with surgery to maximize outcome.

Severe axillary contractures are difficult to treat (Fig. 43-12). For tight bands formed near unburned skin, five flap releases are used (44). Local flaps are often used if anterior or posterior axillary fold contractures are present (39). Contractures that are broader and involve the entire axilla require fasciocutaneous or similar flap procedures (45).

Contractures at the elbow are often complicated by heterotopic ossification (HO) and this is taken into consideration during the surgical plan (46). A Z-plasty or five flap release is used to treat a thin band of scarring (45). Surgical intervention for hand contractures requires expertise and experience. Full-thickness grafts are commonly used. Correction of flexion contracture of the MCP joint has a higher success rate than an extension deformity. K wires are placed for 2 to 4 weeks after surgery for joint stabilization (47). Like the MCP joint,

**FIGURE 43-12.** Axillary release with grafting for treatment of shoulder contracture from burn injury.

extension contractures of thumb exhibit poor outcomes. Contractures associated with dislocated or subluxed joints have the worst results (45,48,49).

In recent years, face transplantation has garnered significant interest in the lay press. The first reported human face transplantation was performed in 2005 (50). To date, there are only a few case reports in the literature (50–52). These investigators utilize a cadaveric facial allograft that requires lifelong immunosuppressive treatment. There are unresolved questions regarding ethical, immunological, and psychological issues. Does the improvement in quality of life justify the long-term risks of immunosuppression, including cancer, infection, and renal toxicity? Will the recipient experience graft rejection? What are the psychological consequences of a transplanted face? These and other issues are only beginning to be addressed in the literature (53–55).

## COMPLICATIONS

Burn survivors experience a wide range of complications that include neurologic, orthopedic, dermatologic, metabolic, pain, and psychosocial problems. These complications may develop in few months to years after injury. The physiatrist plays an instrumental role in managing these problems, both on the wards and in the clinic.

## NEUROLOGIC INJURIES

### Localized Neuropathies

Peripheral mononeuropathies and plexopathies are common in severely burned patients. However, this complication is underreported in the literature, as the diagnosis is often delayed or missed entirely. The neurologic assessment is complicated by the complexity of medical problems and impaired consciousness of the critically ill patient. The reported incidence of peripheral neuropathy ranges from 11% to 30%. Kowalske et al. (56) examined 572 burn survivors and found that electrical injury, history of alcohol abuse, and length of intensive care unit stay were significant risk factors for the development of mononeuropathies. It is also felt that elderly and diabetic patients are predisposed to peripheral nerve compromise (57,58). Compression and stretch of peripheral nerves places them at risk for injury. Bulky dressings can cause compression to superficial peripheral nerves. Improper and prolonged positioning is also a risk factor. Clinical pearls of specific mononeuropathies and brachial plexopathy are reviewed below (Table 43-4).

Several bed and intraoperative positions may put the brachial plexus at risk for injury. Brachial plexus stretch injury likely occurs in patients positioned supine with shoulders abducted at least 90 degrees and externally rotated (59). This position may be used in the surgical suite for grafting of the axilla or lateral chest wall. This position may also be implemented to decrease arm edema or prevent an axillary

**TABLE 43.4** Localized Neuropathies and Associated Risk Factors

Neuropathy	Risk Factors
Brachial plexus	Shoulder abduction >90, external rotation Axilla/lateral chest wall grafting position
Ulnar nerve	Elbow flexion 90 degrees, pronation, tourniquet paralysis
Radial nerve	At spiral groove: resting on siderails, hanging over edge of operating table, tourniquet paralysis At wrist: wrist restraints
Median nerve	Edema, prolonged or repeated wrist hyperextension, tourniquet paralysis
Peroneal nerve	Frog leg position, lateral decubitus position, metal stirrups, leg straps, bulky dressings
Femoral nerve	Hematoma at femoral triangle, retroperitoneal bleed

contracture. To prevent compression or stretch injury to the brachial plexus, it is recommended to position the patient supine with 30 degrees of shoulder horizontal adduction (58).

In the upper extremity, mononeuropathies include the ulnar, median, and radial nerves. The primary area of involvement of the ulnar nerve in the burn patient is at the elbow in the cubital tunnel. The position of elbow flexion and forearm pronation stretches the nerve and places it at risk for compression at this point. Most injuries to the median nerve occur at the wrist level and may be caused by edema and prolonged or repeated hyperextension of the wrist that compresses the nerve at the carpal tunnel. Sustained stretch to the wrist in a hyperextended position, either with splints or in exercise programs, should be performed with caution. The radial nerve is most commonly compressed at the spiral groove of the humerus. Injuries at this level often result from arm resting on the siderails or hanging over the edge of the operating table. The superficial cutaneous branch of the radial nerve may be compressed by restraints at the wrist. This pure sensory neuropathy is a less frequent injury.

In the lower extremity, mononeuropathies may include the peroneal and femoral nerves. Peroneal nerve injuries are relatively common. Stretch injuries are associated with the frog leg position, defined as an externally rotated and flexed hip, flexed knee, and inverted foot. This position is often the result of a short bed, or tender medial thigh, or perineum burns. Compression injuries of the peroneal nerve at the fibular head are associated with the lateral decubitus position, metal stirrups, leg straps, and heavy bulky dressings. Windowing of dressings over the fibular head helps relieve pressure. Femoral nerve injury is uncommon. Injury may occur in the femoral triangle by compression from a hematoma caused by venous or arterial blood draw. Retroperitoneal hemorrhage should be considered in patients with a new femoral nerve injury who are on anticoagulation or have had recent abdominal surgery (60).

The pneumatic tourniquet used to establish a bloodless field in the operating room may cause nerve injury. Improper tourniquet inflation pressure can cause a direct pressure injury of the nerve at the cuff edge (61). The radial nerve is most vulnerable, but ulnar and median nerves are also at risk.

### Peripheral Polyneuropathy

Generalized peripheral polyneuropathy is a similarly common neurologic disorder in burn injury. The incidence ranges from 15% to 30% (57,62,63). Kowalske et al. (56) found that age and length of intensive care unit stay are risk factors for developing polyneuropathy. Polyneuropathy is more commonly seen in those with greater than 20% TBSA burns and electrical injuries (64–66). The etiology of peripheral neuropathies is uncertain; however, metabolic complications and neurotoxic drugs have been implicated. Electrophysiologic evidence of polyneuropathy is seen within 1 week of severe burn injury (67). The patient may have symptoms of paresthesia and signs of mild to moderate weakness in the muscles of the distal extremities. On manual muscle testing, most patients eventually recover their strength, although they may complain of easy fatigability for years after the burn (57,62,63). Critical illness neuropathy is not explicitly documented in the burn literature. Clinically, severely burned patients who commonly experience prolonged intensive care unit stays, sepsis, and multiple organ failure are at risk for critical illness neuropathy.

### Mononeuritis Multiplex

Mononeuritis multiplex is an asymmetric sensory and motor peripheral neuropathy that involves two or more isolated peripheral nerves. The pathophysiology is not well understood, but is thought to result from a combination of circulating neurotoxins, metabolic factors, and mechanical compression. Multiple mononeuropathy was documented in 7 of 121 subjects with greater than 40% burns in one study (68). In a separate study, mononeuritis multiplex was the most common diagnosis in burn patients with a neuropathy (65). At 1 year after injury, lower-extremity nerve lesions demonstrated better functional recovery than upper-extremity nerve lesions (68).

### Pruritis

Itch is a significant complaint for many patients. The prevalence of pruritis is as high as 87% at 3 months and 70% at 1 year after injury (69,70). The mechanism of pruritis is not well understood. Some investigators believe that it is related to axonal sprouting in the dermis. Predictors of pruritis include deep dermal injury, extent of burn, and early posttraumatic stress symptoms (70,71). Various treatment regimens have demonstrated a decrease in reported itch symptoms; however, such interventions lack strong empirical evidence. Nonetheless, there exist multiple clinical treatment options. Topical moisturizers (72) and scar massage (73) are used in clinical practice on healed burn wounds. Topical medications include antihistamines and pradoxin, a tricyclic antidepressant. Oral medication options also include antihistamines (74) and pradoxin (DPT Laboratories, San Antonio, TX).

**FIGURE 43-13.** Burn contracture of the elbow.

There are reports of the use of transcutaneous electrical nerve stimulation (TENS) and topical anesthetics in the treatment of pruritis (75,76). For those with severe itching, often a combination of interventions is needed to control symptoms.

## BONE AND JOINT CHANGES

### Contractures

Contractures are defined as an inability to perform full ROM of a joint. They result from a combination of possible factors—limb positioning, duration of immobilization and muscle, soft tissue, and bony pathology. Individuals with burn injuries are at risk for developing contractures. Burn patients are often immobilized, both globally, as a result of critical illness in the severely burned, and focally, as a result of the burn itself due to pain, splinting, and positioning. Burns, by definition, damage the skin and may also involve damage to the underlying soft tissue, muscle, and bone. All of these factors contribute to contracture formation in burn injury.

Contractures place patients at risk for additional medical problems and functional deficits. Contractures interfere with skin and graft healing. Functionally, contractures of the lower extremities interfere with transfers, seating, and ambulation. Contractures of the upper extremities may affect ADL, such as grooming, dressing, eating, and bathing, as well as fine motor tasks.

Approximately 40% of hospitalized burn patients develop contractures. The shoulder, elbow, and hand are the most

commonly involved joints (Fig. 43-13). Those with more extensive burns, amputations, and inhalation injuries are more likely to develop severe contractures (77). Positioning and ROM exercises are the mainstays of contracture prevention (18,78). Positions of comfort often include joint flexion and adduction and lead to contracture formation. For the bedbound burn patient, the ideal position to prevent contractures involves neck extension, shoulder abduction and external rotation, elbow extension and supination, hip abduction, and ankle dorsiflexion (see Fig. 43-8). Such positioning is coupled with regular ROM exercises. Once a patient has developed a contracture, treatment usually begins with conservative measures, including splinting (79–86) and serial casting (15,16,87). Richard et al. studied 52 patients with burn contractures, comparing treatment with a multimodal approach (massage, exercise, pressure) to a progressive approach (splinting and serial casting). Contractures corrected in less than half the time in the progressive compared to the multimodal treatment group (83). In another study, Bennett et al. performed a case series of 15 subjects, with 35 contractures treated with serial casting for a mean of 13 days. They found a mean increase in ROM from 56% of normal before casting to 86% of normal after casting (15). Some investigators have reported success using ultrasound (88) and silicone gel (89,90) in treating contractures. Surgical correction of contractures (41,91) is reserved for contractures that significantly impact one's function and are not improved by conservative measures.

## Bone Growth

Significant growth delays occur in children after a severe burn injury (92). Growth disturbances in pediatric burns survivors may result from premature fusion of the epiphyseal plate of affected long bones. Bone growth issues should be considered in growing children with burn scars that cross a joint and with joint contractures. Partial epiphyseal plate fusion may cause bone deviation and deformity (93,94). In addition, case reports document that pressure garment for the treatment of facial burn injury in children alters facial bone growth. It is recommended to monitor closely facial development during and after pressure garment use in children for the development of normal dental and facial proportions (95,96).

Children with burn greater than 15% TBSA exhibit decreased bone mineral density early (at 8 weeks) after injury and the loss is sustained (5 years after injury) (22). The mechanism for loss of bone mass is still being worked out; however, recent research demonstrates causal roles for multiple factors including increase in endogenous glucocorticoids, resorptive cytokines from the systemic inflammatory response and vitamin D deficiency and disruption of calcium metabolism. Reduced bone density places children at risk for long bone fractures (97–99). Mayes et al. examined 104 burned children with greater than 40% TBSA and found a 5.8% incidence of fracture (100). Investigators have studied the use of recombinant human growth hormone without proven effect on bone formation (101). Recent studies have demonstrated improved bone mineral density with bisphosphonate therapy. Klein et al. performed a randomized controlled trial of 43 children with greater than 40% TBSA and examined the effects of acute administration (within 10 days of injury) of intravenous pamidronate. Subjects receiving pamidronate demonstrated higher whole body and lumbar spine bone mineral content at discharge, 6 months and 2 years compared to controls (102,103).

## Osteophytes

Evans and Smith report that osteophytes are the most frequently observed skeletal alteration in adult burn patients. They are most often seen at the elbow and occur along the articular margins of the olecranon or coronoid process (104,105).

## Heterotopic Ossification

HO is the abnormal formation of bone in soft tissue. The incidence of HO is estimated at 1% to 2% of hospitalized burn patients (106–108). Only those with symptomatic joints, impaired ROM, joint pain, or other symptoms, underwent radiographic examination. Therefore, reports in the literature reflect the incidence of clinically significant HO, not the true incidence. The etiology of this process is unknown. The elbow is the most frequent joint affected, comprising greater than 90% of cases in a 21-year review (106). Risk factors associated with the development of HO include size of burn, ventilator support, intensive care unit stay, prolonged wound closure, wound infection, and graft loss (106,109).

HO may occur as early as 5 weeks but usually develops at around 3 months after injury. One of the earliest signs of HO is loss of joint ROM. Other clinical findings may include swelling, erythema, pain, and peripheral nerve injury. Symptoms may precede radiologic findings. A bone scan is the most sensitive diagnostic imaging test and may demonstrate positive findings up to 3 weeks prior to positive radiographic findings.

Treatment of HO begins with conservative measures, including positioning and ROM to prevent worsening of joint motion. There is no evidence in the literature to support HO prophylaxis for burn patients. Timely surgical intervention is indicated when HO results in nerve entrapment. Surgical treatment is also indicated for HO that causes significant functional deficits, including impairments in upper- and lower-extremity function, impaired mobility and ADL. In these cases, it is common practice for surgeons to wait until the bone is mature to operate, which can take 12 to 18 months. One can follow the HO with serial radiographs every few months to monitor for bone stabilization. Surgical excision of HO at the elbow results in improvement in ROM (110,111). Tsionos et al. performed HO in 28 subjects and 35 elbows at a mean of 12 months after injury. At a mean follow-up of 21 months, the flexion/extension improved from 22 degrees preoperatively to 123 degrees postoperatively (110). In a separate study of eight children with elbow HO, at 17 months after surgery all subjects demonstrated improved ROM and all were able to reach their face and perineum for functional tasks of feeding and toileting (111).

## Bony Changes in Electrical Burns

New bone formation is found at residual limb long bones in electrical burn survivors with amputation. Bony changes in the electrical burn include bone splitting, bony necrosis, bone swelling, lucent holes in bone, and periosteal new bone formation (112). Helm et al. reviewed 61 amputation sites in 43 burn survivors with electrical injuries. Twenty-three of twenty-eight patients with long-bone amputations developed new bone formation at the amputation site. No new bone growth was evidenced in the 15 subjects with small bone amputations and disarticulations. The average time from amputation to diagnosis of new bone was 38 weeks. Of those with new bone formation, 12% required surgical revision of the stump and 7% required replacement of their prosthesis secondary to new bone formation. The etiology of new bone formation in the electrical amputee is unknown (113).

## Scoliosis and Kyphosis

Asymmetric burns of the trunk, hips, and shoulder girdle can cause the patient to favor the affected side. In the growing child, the contracture of burn scars and resultant postural change can result in structural scoliosis. Investigators have reported a case series of four children scalded on the back as infants that developed adolescent scoliosis. The deformities of all four cases were corrected surgically with good results (114). Similarly, childhood burns on the anterior neck, shoulders, and chest wall may produce a rounding of the shoulders and

sunken chest. Likewise, burn scar shortening and protective posturing can result in kyphosis. Both scoliosis and kyphosis are amenable to bracing and surgical interventions. An orthopedic surgeon should follow such survivors.

### Septic Arthritis

Septic arthritis is challenging to diagnose in the severely burned patient. The characteristic signs and symptoms are often absent or masked by the overlying burn wound. Joint pain, swelling, color change, and tenderness are common symptoms at the site of burn injury or grafting and therefore are difficult to distinguish from septic arthritis.

The two major causes of a septic joint are penetrating burns into a joint and hematogenous seeding in cases of bacteremia. Burn patients are at risk for infection because of their impaired immune system and concurrent illness. Septic arthritis may cause gross dislocation because of capsular laxity or cartilage and bone destruction (115), or it may result in severe restriction of movement or ankylosis. It occurs most frequently in the joints of the hands, hips, knees, and wrists.

### Subluxations and Dislocations

Joint subluxation of the hands and feet are common after burn injury. Burns of the dorsal surface may contract resulting in joint hyperextension. With prolonged hyperextension, the joint can sublux. This is most commonly seen in the MCP and metatarsophalangeal (MTP) joints. Ulnar neuropathy places the patient at additional risk for subluxation of the fourth and fifth digits. For dorsal hand burns, prevention of subluxation is achieved with a combination of splinting and ROM exercises. A dorsal hand burn splint places the MCP joints in 60 to 90 degrees of flexion and the distal interphalangeal (DIP) and proximal interphalangeal (PIP) joints in full extension. Similarly, the MTP joints may become subluxed after contraction of healed wounds, especially in children. Application of surgical high-top shoes with a metatarsal bar keeps the toes in an antideformity position.

Posterior hip dislocation can be a problem in children. Hips maintained in an adducted and flexed position are at risk for dislocation. Anterior shoulder dislocations occur in positions of abduction and extension. Shoulder dislocations may result from positioning in the operating room (116).

## PAIN COMPLICATIONS

Pain management is integral to the care of the burn survivor. In the acute stage after partial-thickness burn, some nerve endings in the dermis remain intact resulting in significant pain at the site of injury. In contrast, after full-thickness burn the nerve endings are completely destroyed and the burned area is less painful or painless. Treatment of burns with daily dressing changes that debride necrotic tissue causes significant procedural pain. Patients may report unbearable levels of pain (117). It is important to manage the constant background pain of the burn injury itself as well as the intermittent procedural pain.

It is well documented that hospitalized burn patients' experience of pain varies among patients and across patients over time (118–120). Therefore, it is important to tailor the pain management plan for each individual. A few guiding principles are accepted as good clinical practice. Background pain can be treated with a continuous infusion of opioids, a long-acting oral opioid, or patient-controlled analgesia. Procedural pain is well managed with short-acting opioid medications scheduled prior to the procedure (121,122). In a randomized controlled trial of 79 hospitalized burn survivors, Patterson et al. (123) found that adding lorazepam to the standard opioid pain medication significantly reduced pain levels during procedures for those with high baseline pain.

Nonpharmacological interventions are important adjunctive interventions to standard pain medication regimens. This is an area of increasing interest in recent years. Simple environmental modifications and consistency are helpful. The goal is to create a calm atmosphere that incorporates as much patient autonomy as possible. Patients should be encouraged to direct their own dressing care. Some find the presence of family members and music helpful. The treatment team should provide consistent timing, staff, and routine of procedures. Investigators have found some success in the use of hypnosis to decrease procedural pain in burn injury (124,125). Patterson and Ptacek performed a randomized controlled trial of 61 hospitalized severe burn patients, comparing hypnosis with a control intervention that includes attention, information, and brief relaxation instructions prior to dressing changes. For those with high baseline pain levels, the hypnosis group reported less posttreatment pain (124). Virtual reality has demonstrated success as a distraction technique to help assuage pain during wound care (126–128). Sharar et al. performed a randomized controlled within-subject trial of 146 treatment comparisons among 88 subjects. Compared with standard analgesic therapy alone, the addition of virtual reality distraction resulted in significant reductions in subjective pain ratings, including intensity (20% reduction), unpleasantness (26%), and time spent thinking about pain (37%) (128). Other nonpharmacological interventions that are validated in the literature include massage therapy for both acute and chronic pain in burn patients (73,129).

Neuropathic pain after burn injury is not well categorized in the literature. Neuropathic pain is defined as pain initiated or caused by a primary lesion or dysfunction in the peripheral or central nervous system. Neuropathic pain symptoms consisting of pins and needles, burning, stabbing, shooting, or electric sensations are common complaints of burn patients following healing of their open wounds. In two studies examining a total of 534 burn patients at least 1 year after injury, 71% and 82% reported paresthetic sensations in their burn scar, respectively. These sensations were associated with burn size and skin grafting (130,131). Schneider et al. retrospectively reviewed 72 patients with complaints of neuropathic pain and characterized their clinical course. Neuropathic pain symptoms first occurred at a mean of 4 months and persisted until 13 months after injury. Documented initial pain severity

score was 7 out of 10. Typical exacerbating factors included temperature change, dependent position, light touch, and weight-bearing activities. Common alleviating factors included rest, massage, compression garment use, and elevation (132). Common treatment regimens include gabapentin, opioids, and steroid injections into areas of symptomatic hypertrophic scar. Two case reports discuss successful treatments of neuropathic pain, one using methadone and the other an implanted peripheral nerve stimulator (133,134).

## SKIN COMPLICATIONS

### Hypertrophic Scarring

Hypertrophic scarring can result from deep partial- and full-thickness burns. The scarring first presents as a firm, red area of healed burn scar. It progresses over weeks to become raised, erythematous and rigid (Fig. 43-14). Scars can contract and if present over a joint, can contribute to contracture formation. Over time scars mature, taking on a pale, more pliable and less thick appearance. This process may take up to 2 years. Scarring can result in significant impairments in function. In addition to physical impairments, hypertrophic scarring may lead to psychosocial consequences. Scarring can impact self-esteem, social isolation, body image, and community reintegration (135,136). It is one of the most significant long-term complications of burn injury.

Histologically, scars demonstrate a whorled collagen pattern, in contrast to the parallel array of collagen fibers in normal skin. Scar tissue exhibits a proliferation of fibroblasts

and capillaries, thickened epidermis, and a lack of rete pegs. Endothelial cell proliferation results in occlusion of the microvasculature leading to a local hypoxia. With maturation, the microvasculature degenerates and capillaries are reabsorbed (137–139). There exists a broad range of clinical presentations of scars that include varied thickness, color, rigidity, and corresponding symptoms. The prevalence of hypertrophic scarring is estimated at greater than 60% of white and greater than 75% of nonwhite survivors with severe burns (140). Interestingly, scarring is not documented in neonatal, elderly, and morbidly obese burn survivors. Prevalence data is confounded by lack of a standardized objective measure of hypertrophic scarring. The Vancouver Scar Scale is the most common method of measurement; however, it is comprised of subjective ratings of pigmentation, vascularity, and pliability and as a result has a relatively low interrater reliability (141). Risk factors for the development of hypertrophic scarring include open wounds for greater than 2 to 3 weeks, burns that require grafting, and heavily pigmented individuals (142). The etiology of hypertrophic scarring is largely unknown.

There exists little evidence in the literature to support specific treatment strategies for hypertrophic scarring. Current studies limitations include sample size, randomization, adequate follow-up, and objective outcome measures. Given the seriousness of the problem, investigators are actively pursuing research in this area (143). Meanwhile, providers rely on clinically derived treatment approaches. Management begins with early identification of hypertrophic scarring and those at risk of scarring. Initial conservative treatment measures include splinting, scar massage, exercise, and positioning. Pressure therapy

**FIGURE 43-14.** Hypertrophic scarring of the hand. Note the raised and rigid appearance of the scar.

constitutes the main treatment intervention. It is postulated that pressure (at least 25 mm Hg) inhibits capillary blood flow resulting in local ischemia. A decrement in tissue metabolism leads to impaired fibroblastic activity and enhanced collagenase activity. Apoptosis ensues with release of proteases and liposomal contents (43,144).

The goal of therapy is to arrest scar development and flatten existing scars. Initially, pressure wrappings are applied around the affected areas using plastic elastic (ACE), cotton elastic (tubigrip) or adhesive elastic (coban) bandages. As edema resolves the scarred area assumes a more stable shape and custom-made pressure garments are fit. It is recommended to wear compression garments 23 hours of the day until the scar matures, which can be up to 2 years (145). Compliance with this regimen is difficult. The garments are warm, socially awkward, and difficult to don. They stretch and shift with wear, and replacement garments are recommended every 3 months. Concave areas are poorly compressed. To improve fit or pressure over areas with challenging contour features, such as the digital web space, silicone sheets or gels, sponges, or conformed pieces of plastic are used to improve the delivery of pressure and limit shear over the new and fragile epithelium (43,146,147).

Chang et al. performed a randomized controlled trial comparing pressure garment therapy to no pressure garment therapy in 122 consecutive patients with hypertrophic scarring. No significant differences in Vancouver Burn Scar Assessment Scale were found between the two groups (148). In another randomized controlled trial, investigators compared high-pressure (elastic nylon) to low-pressure (elastic cotton) treatment of hypertrophic scarring and found no significant difference in scar outcome (149). Both studies utilized subjective outcome measures to determine the number of days to scar maturation or the number of days for pressure therapy. The efficacy of pressure therapy is unknown; however, there are no major treatment alternatives. Future research in this area will greatly advance the care of burn survivors.

In addition, pressure therapy may have detrimental effects. Obstructive sleep apnea has been described in two patients secondary to pressure garments used to treat severe facial and upper-body burns. Obstructive sleep apnea was confirmed by complex sleep polysomnography, and documented desaturations significantly improved with removal of the garments (150). In children, hypertrophic scarring of the head and neck and pressure garment treatment have been reported to cause deformities. Knowledge of such potential complications helps inform treatment decisions. Scar contractures of the mandible may lead to dental occlusion and difficulty with lip closure and subsequent drooling. Pressure garments at the mandible may cause mandibular hypoplasia. Severe neck scarring and resultant contractures may elongate the mandible. Mouth burns are associated with dental changes, including cross bite, crowding, and bite retrusion. Pressure garments may affect facial growth and development of normal contours (151).

Other treatments, silicone gel and massage, have been examined in the literature as well. Ahn et al. investigated the

efficacy of an 8-week course of topical silicone gel in ten adults with hypertrophic scars. Each subject acted as their own control; mirror image or adjacent scars were untreated controls. Based on elastometry, skin biopsy, texture, color, thickness, durability, and itching, the silicone-treated areas demonstrated greater improvements than control scars at 4, 8, and 12 weeks (152). This suggests that silicone gel may be an effective intervention for hypertrophic scars. A study of 30 pediatric burn patients examined the use of frictional massage 30 minutes a day over a 3-month period. No significant effects were demonstrated with regard to the vascularity, pliability, and height of the hypertrophic scar (153).

## Blisters

Blisters are a common complication of partial-thickness burns. Blisters result from inflammatory changes after injury that increases capillary permeability, thereby permitting fluid accumulation between the epidermis and dermis. Management of blisters is a controversial topic in burn care. Sargent performed an extensive literature review on the topic, examining issues related to the care of blisters, including infection, healing, function, aesthetics, patient comfort, dressing care, and cost-effectiveness. The author issued clinical practice guidelines for management of blisters in partial-thickness burns. Small blisters (<6 mm) may be left intact, as they are unlikely to rupture spontaneously, damage underlying tissue, or impede healing. Large blisters (>6 mm) should be debrided. Thick-walled blisters on palms and soles of feet need not be debrided as they are less likely to become infected, and debridement may cause patient discomfort and impaired mobility. Debridement of blisters is associated with faster wound healing and decreased scarring. Decreased scarring is also associated with use of temporary skin substitutes to cover the debrided site (154).

## UV Sensitivity and Skin Pigmentation

Sun protection is essential for burn survivors. The area of burn injury is susceptible to further damage from ultraviolet radiation from the sun. It is recommended that burn survivors of deep partial- and full-thickness burns avoid and protect against sun exposure for the first few years after injury. Especially after burn injury, people of all different skin pigmentation are at risk for sunburn from ultraviolet radiation. Avoiding direct sun exposure, especially during midday hours when ultraviolet exposure is highest, minimizes risk of sunburn. Covering sites of burn injury with clothing for at least the first year after injury is recommended. In addition, sunscreen with a sun protection factor of 15 or greater should be applied to healed burn sites prior to any sun exposure (155).

Pigmentation changes are common after burn injury. Two studies followed patients longitudinally after superficial partial-thickness burn injury and found that subjects developed hyperpigmentation by spectrophotometry measurements at the burn site. Hyperpigmentation correlated with premorbid skin color, age, sun exposure, and time after injury (156,157). Deep partial- and full-thickness burn injuries may result in hypopigmentation or depigmentation. Dyspigmentation

after burn injury can be treated surgically. Al-Qattan reported treating 15 subjects with hyperpigmented skin grafts of the palm and digits with surgical excision and split-thickness skin grafts. He also treated eight subjects with hypopigmented burn sites of the palm, digits, and forearm with dermabrasion and thin split-thickness skin grafts. The hyperpigmentation group exhibited color and texture match and all subjects were satisfied. The hypopigmentation group demonstrated slight hyperpigmentation of the graft site; however, all subjects were satisfied with the results (158). Other investigators demonstrated good results by treating depigmented burn scar using a carbon dioxide laser for dermabrasion followed by split-thickness skin grafting (159).

### Malignancy

Development of malignant tumors in chronic burn wounds or scars is extremely rare, but is a frequently reported complication. Most tumors are squamous cell carcinoma; basal cell carcinoma and malignant melanoma are less common. Diagnosis ranges from 20 to 30 years after burn injury. Two recent large cohort studies followed 16,903 and 37,095 burn survivors, respectively, for a mean of 16 years. There was no increased risk for squamous cell carcinoma, basal cell carcinoma, or malignant melanoma in the burn survivors compared to the general population. In addition, subgroup analysis of those with more severe burns and longer follow-up exhibited no increased risk for skin cancer (160,161).

## METABOLIC COMPLICATIONS

### Catabolic State

Patients with burns greater than 40% TBSA experience a hypermetabolic response for at least 1 year after injury. Catabolism contributes significantly to morbidity and mortality. The catabolic state in burn injury is associated with impaired wound healing, increased infection risk, loss of lean body mass, slowed rehabilitation, and delayed community reintegration. Pharmacologic and nonpharmacologic strategies are implemented to help reverse the effects of catabolism. Nonpharmacologic interventions include early burn wound excision and closure, aggressive treatment of sepsis, maintenance of thermal neutrality by elevation of the ambient temperature, high carbohydrate, high protein diet, and early institution of resistive exercises. Pharmacologic interventions may include use of recombinant human growth hormone, low-dose insulin infusion, synthetic testosterone analog (oxandrolone), and  $\beta$ -blockade (29,101,162,163).

The benefits of oxandrolone on hypermetabolism in burn injury are well supported by multiple well-designed studies in recent years. Jeschke et al. performed a prospective randomized controlled trial of 235 burned children with greater than 40% TBSA. Subjects receiving oxandrolone for at least 7 days during acute hospitalization exhibited shorter length of intensive care unit stay and higher lean body mass than controls (164). When oxandrolone was given to children for 1 year after

severe burn, subjects demonstrated continued improved lean body mass, bone mineral content, muscle strength, height, and weight compared to controls (165). A separate multicenter prospective randomized controlled trial of 81 adults with 20% to 60% TBSA was stopped early because of significantly shorter length of stay exhibited by the oxandrolone group compared to controls (166).

### Temperature Regulation

Full-thickness burns damage the sweat glands of the dermis. Despite treatment with skin grafting, the sweat glands are not replaced or regenerated. Impaired sweating may affect thermoregulation (167), particularly with those with larger TBSA burns. Patients with large burn injuries often report overheating and exaggerated sweating response in areas of unburned skin with exercise and heat. Such complaints may interfere with burn survivors exercise tolerance, overall fitness and health, as well as occupational reintegration (168).

Austin et al. studied the effects of exercise on thermoregulation in six burn survivors with greater than 30% burn injuries and three nonburned controls. Subjects exercised for 1 hour on a cycle ergometer with an ambient temperature of 35 degrees centigrade. Subjects with burn injuries tolerated moderate exercise. The burn subjects maintained their heat tolerance by increasing sweat rates in areas of unburned skin (169). In another study, subjects with larger burns (mean 49% TBSA) performed bench stepping in a 40 degree centigrade environment for 3 hours. Despite a high sweat rate from their unburned skin, the severely burned subjects were unable to maintain body temperature compared to nonburned controls (170). Children appear to tolerate a short duration of moderate exercise. McEntire et al. studied 15 children with severe burns (>40% TBSA) and compared them with 13 healthy children controls. Subjects completed 20 minutes of treadmill exercise at approximately 75% of their peak aerobic power. There was no significant difference in body temperature between the severely burned children and controls (171).

## PSYCHOSOCIAL ISSUES

Psychosocial complications after burn injury are common and present major obstacles to burn survivors' rehabilitation and community integration. Burns are traumatic, functionally impairing, excruciatingly painful, and disfiguring. All of these factors contribute to the prevalence of psychosocial complications after burns. In addition, premorbid psychiatric history is higher in burn patients than in the general population. Approximately one third of burn injuries are associated with concomitant alcohol or drug use (6). Preinjury psychiatric problems, including anxiety, depression, and other problems, are more common in burn patients than in the general population and have been documented at 28% to 75% (172). Common psychosocial issues after burn injury include posttraumatic stress, depression, anxiety, sleep disorders, and

community integration. The research community has excelled in identifying and describing these important psychosocial issues after burn injury; however, at the time of this publication few studies have examined treatment interventions. Future investigation in this area is needed.

### Posttraumatic Stress

Posttraumatic stress occurs after one experiences a traumatic event with the threat of injury of death to self or others. Three types of symptoms characterize posttraumatic stress disorder (PTSD): reexperiencing the event, avoidance of reminders of the event, and an increased state of arousal. For the diagnosis of PTSD symptoms must be present for greater than 1 month, and for acute stress disorder symptoms must be present for greater than 2 days during the first 4 weeks after the event. Over one half of burn survivors report posttraumatic stress symptoms at 1 day, 1 month, and 1 year after injury. Commonly reported symptoms include sleep disturbance, recurrent and intrusive recollections of the injury, avoidance of thoughts or feelings associated with the burn, and distress at reminders of the burn. Twenty-one percent of subjects at 1 month and 19% of subjects at 1 year met full criteria for PTSD. Overall, posttraumatic stress symptoms decrease over time. It is common for burn survivors to endorse some posttraumatic stress symptoms but not fulfill the diagnostic criteria for posttraumatic stress and acute stress disorders (173). Risk factors for the development of PTSD after burn injury include posttraumatic stress symptoms at earlier time points, female gender, social support, and the size and location of burn injury (174). Treatment interventions for posttraumatic stress have not been validated in the literature. Nonetheless, screening for posttraumatic stress symptoms and referral for pharmacological and nonpharmacological treatment interventions are recommended.

### Depression

Depression is a similarly common psychiatric problem after burn injury. One group of investigators reported the prevalence of moderate to severe depression symptoms using the Beck Depression Inventory at 53% at 1 month, 34% at 1 year and 45% at 2 years after injury (175). Premorbid psychiatric problems, head or neck burns, length of hospital stay, and female gender are risk factors associated with depression (175,176). Edwards et al. followed 128 burn survivors and found that one third of subjects reported some form of suicidal ideation during the first year after injury. Pain severity at discharge was the only significant predictor of suicidal ideation (177). The frequency of suicidal ideation highlights the importance of early identification of symptoms in suicide prevention. Furthermore psychosocial outcomes are complex and multifaceted. Pain management may impact depression and other psychiatric complications. There are no treatment studies to date for depression in burn injury. Clinicians should identify those at risk for depression and those with depressive symptoms and provide appropriate treatment options.

### Sleep Disturbances

Sleep disturbances may be related to a psychiatric problem, medical issue, or a direct consequence of the burn injury. As many as 74% of burn survivors reported sleep problems at 1 week after discharge from the hospital. Common problems include nighttime awakenings, daytime napping, nighttime pain, and difficulty with sleep onset (178). Sleep problems, such as insomnia and nightmares, persist at 1 year after injury (173). Gottschlich et al. examined polysomnography in 11 severely burned inpatient children over forty-three 24 hour sessions. Deep sleep (stages III and IV) and rapid eye movement were completely missing in 40% and 19% of recordings, respectively. This demonstrates altered sleep architecture in the acute period after burn injury (179). In a separate study of hospitalized burned adults, investigators found that sleep duration was 5.5 hours with numerous awakenings. In addition, significant temporal relationships were documented between sleep, pain, and analgesic medications. A lack of sleep one night was associated with increased pain complaints the following day and increased analgesic intake. High levels of pain and analgesic intake during the day were associated with poor sleep the following night (180).

It is important to ask burn patients about their sleep. Since other psychiatric problems can contribute to sleep problems, clinicians should consider these issues as well when treating sleep disorders in burn injury. Treatment of pain, pruritis, depression, and posttraumatic stress and anxiety may improve burn survivors' sleep.

### Community Integration

The ultimate goal of rehabilitation is reintegration into society, including a return to one's work, school, and recreational and community activities. The various physical and psychological complications of burn injury detailed above may result in significant impairments that hinder community integration. In a study of 463 burn survivors who completed the Community Integration Questionnaire, researchers found significant problems in home integration, social integration, and productivity. Home integration was best predicted by gender and living situation; social integration was best predicted by marital status; productivity was best predicted by burn severity, age, and pre-burn job satisfaction (181). Brych et al. followed 363 burned adults who were employed at the time of injury and found that the mean time off work was 17 weeks. Sixty-six and ninety percent of survivors returned to work at 6 and 24 months, respectively. However, a subgroup analysis found that only 37% returned to the same job, with the same employer, without accommodations (136). This more detailed data underscores the severity of job disruption after burn injury. Factors associated with unemployment after burn include severity of injury, extremity burns, premorbid psychiatric history, and premorbid unemployment (136,182,183). Esselman et al. examined barriers to return to work in 154 burn survivors using a survey administered 16 times over 1 year. At 1 year, significant barriers included physical abilities, psychosocial factors (nightmares, flashbacks, body image), and working conditions (humidity, temperature, safety) (168).

Some burn survivors experience permanent impairment as a result of their injury. The American Medical Association publishes guidelines for determining the extent of impairment. Impairment is graded as a percentage of whole body impairment. In the sixth edition of the guidelines, impairment in burn injury is primarily dependent upon the following factors: the severity of the skin condition; the frequency, intensity, and complexity of symptoms and the treatment regimen; the ability to perform ADL. This impairment rating may be modified by objective physical examination findings, facial disfigurement, and related impairments of other organ systems including musculoskeletal, respiratory, cardiovascular, endocrine, and gastrointestinal. It is important to remember that these guidelines are intended for evaluation of patients with permanent impairments, those who have attained maximal recovery (184).

## SPECIAL CONSIDERATIONS

### Pediatric Burns

The physiologic and anatomic differences between adults and children need to be considered during acute and long-term medical management after burn injury. Children are not small adults. Anatomically, the pediatric trachea is shorter, the glottis is more anterior, and the diameter of the airway is smaller compared to an adult (185). These anatomic differences are important during intubation and in the presence of facial burns, upper airway damage, or edema. Children have an increased risk of bronchospasm (186). The smaller airways make them more susceptible to occlusion if there is pulmonary debris, such as after an inhalation injury.

After a significant burn injury, children often demonstrate impaired cardiac function. This is particularly relevant if the child is less than 1 year of age, has underlying cardiac anomalies or sustained an inhalation injury (187).

### Pediatric Exercise

The goals of exercise are similar to adults, but the methods are different. Exercises are designed to be compatible with the child's level of development and incorporate play. Toys should be developmentally appropriate for the child. For instance,

nesting blocks for the child less than 2 years old are used to enhance hand function. In an older child, wheelbarrow walking or crab walking stretches the shoulder muscles and strengthens the shoulder girdle. Bicycling and soccer ball kicking are appropriate for lower extremity stretching, strengthening and endurance training in older children. A wide variety of products, such as theraband and therapy putty can provide resistance and facilitate strengthening. Handheld computer games are valuable for fine motor function of the hand. Interactive computer games, such as the Wii, utilize visual monitors and encourage gross motor participation.

### Splints for Children

The skin of infants and children differs from that of adults. Because the skin of children is thinner, full-thickness wounds are more likely to occur (188). Stretching techniques, splint fabrication, and pressure garments (Table 43-5) are designed to accommodate the thinner and more fragile skin of children. Therefore, the treatment of contractures in children is similar to that of adults, with a few modifications.

It is often difficult for parents to stretch a child's joints. Aggressive stretching of contractured joints is often difficult for children to tolerate. Stretching under anesthesia and pain medication administration prior to therapy may be indicated.

When using splints in the pediatric population, one must take into consideration the smaller size of body parts and the quality of the skin. Extra padding or foam may be needed. Compared to adults, children have hypermobile joints; this is also a consideration. Splints in children require frequent evaluation by caregivers because of normal growth.

Many suggest that splints for infants are applied when the child is sleeping and allow active use of the extremity during wakeful periods. If this is insufficient, wearing time is increased during the daytime and splints are removed for exercise or therapeutic activities. Children tolerate prolonged joint immobilization and do not develop joint contractures like adults.

Dynamic splints are an option for adolescents but are generally not tolerated by infants or small children because they are too difficult to keep in place. Small children are better with static splints or serial casting. By age 3 or 4, children may use

**TABLE 43.5** Compression Garments: Considerations in Children and Elders

Pediatrics	Geriatrics
Limited understanding and reasoning	Cognitive concerns
Decreased attention span	May learn more slowly, decreased vision or hearing
Decreased cooperation	Decreased cooperation
Preexisting behavioral problems	Preexisting mental health issue
Locate zippers in locations not easily accessible by the child (e.g., on the back not the chest, use colored garments, blue, etc.)	Consider location of closures and fasteners, avoid closures that are not in easy reach
Need assistance to don or doff	May also need assistance
Small body parts require careful measuring	Arthritic joints requiring special fasteners (e.g., Velcro or zippers)
Rapid growth and high activity (frequent refitting)	May last longer depending on care and activity level

adjustable three-point splints at the knee or elbow. Dynamic ankle splints work in this older group as well.

For young children, hand and ankle splints are made with longer proximal extensions to secure the splint from sliding out of position. For instance, a hand splint may extend to the wrist and forearm. Soft straps that cross the volar aspect of the wrist and forearm secure the device. Splints may need to be covered with a garment, such as a sock, to prevent the child from removing the device. The hand of a young child or infant is typically splinted flat with the wrist in extension, fingers extended and abducted, and the thumb in extension and abducted radially. Sandwich splints lined with foam with a dorsal and ventral component are useful

### Pediatric Reconstructive Surgery

Children often require surgery to restore function. In addition, surgery may be indicated to correct deformities and functional impairments that develop as a result of growth. Scar tissue and some grafts do not elongate with growth and consequently reconstructive surgery is required. If ROM is normal as the child grows, surgery is not indicated. The neck and axillae require close monitoring. Reconstructive surgery is performed approximately 1 year after menarche for girls with significant scarring of the anterior chest.

### Geriatric Burns

In the geriatric population, preexisting physical limitations or medical problems have a greater impact on rehabilitation than in younger survivors. Premorbid functional level and health are particularly important in establishing a geriatric rehabilitation plan. Older adults often have cardiovascular disease. In the face of a serious burn injury, an older patient may develop worsening cardiac function or myocardial infarction (189). There is a baseline decrease in pulmonary function that is associated with aging. Also, many older individuals have underlying pulmonary or cardiac disease that negatively impacts respiratory reserve and function. A burn injury coupled with inhalation injury markedly increases the risk of mortality and morbidity. Principles of cardiopulmonary rehabilitation are included in the exercise plan for these individuals.

### Skin and Wound Healing

The atrophic skin of the elderly is characterized by the absence of rete pegs, a thinner dermis, and a reduced number of skin appendages (190). As a consequence, elderly sustain more severe burns than younger adults from the same injury (191). Additionally, the cellularity of skin decreases with age, leading to a reduced number of macrophages and fibroblasts, thereby prolonging healing time. The skin of the elderly exhibits less turgor than that of younger people and is due in part to a decrease in glycosaminoglycans. The redundant tissue can be harvested for use as full-thickness grafts and improved functional outcome.

Early excision and grafting is a well-established approach to burn injury in children and adults; however, the risk-to-benefit ratio is not as clear in the elderly (192,193). The burn wound

and donor site are additive, effectively increasing the surface area of open wounds resulting in increased rates of morbidity and mortality.

### Exercise

During normal aging, one experiences sarcopenia, or muscle mass loss as well as loss of strength (194). Strength declines at a rate of 15% per decade after age 50%, and 30% after age 70. There is evidence that resistance training can reduce and reverse some of the muscle changes and strength loss of aging (195). However, sarcopenia, and the associated weakness, is aggravated by disuse or bed rest. As a result, elderly are at greater risk for loss of function after burn injury.

A geriatric burn exercise program takes into account one's preexisting musculoskeletal and neuromuscular conditions that influence the exercise prescription. One must determine if passive, active-assistive, or active exercise therapy is appropriate. An exercise regimen includes ROM, stretching, and strengthening.

Stretching principles are similar to those of any adult. Each joint is stretched individually. This progresses to stretching of an entire limb. With redundant tissue present in some body regions, scarring and contracture development are less frequent than in other adults.

ROM exercise is modified in the presence of underlying joint disease, such as degenerative arthritis. A burn injury involving a chronically arthritic shoulder is treated differently than a nonarthritic joint. One may need to modify goals to achieve a functional range rather than full ROM.

Strength training starts slowly and gradually increases in intensity. It is important to closely monitor cardiopulmonary status. As in other age groups, strengthening usually begins with muscles that oppose scar contracture formation. Exercise should advance judiciously beginning with nonresistance exercises and progressing to resistance bands and light weights. Maximal exercise capacity and oxygen consumption decrease with age; however, there is evidence that aerobic capacity can increase with endurance training in the elderly.

### FACIAL BURNS

Skin contractures and scars of the face are challenging to prevent. Facial tissue is highly mobile and has few points of fixation. Common facial deformities include ectropion of the lower eyelid and microstomia of the mouth. The development of ectropion prevents eyelid closing leading to eye irritation that may result in corneal ulcers. Microstomia is a contracture of the mouth that impairs mouth function.

Current review of the literature indicates that rehabilitation interventions for face burns lack general agreement. No generally accepted medical or rehabilitation protocols exist. However, a recent survey indicates that the common treatment methodologies include positioning, splinting, exercise, stretching, and pressure therapy (196).

**FIGURE 43-15.** Microstomia from facial burns.

During the acute phase many begin treatment with splints for the neck, mouth, nose, and ears. Active ROM of the face, including eyes and mouth, is initiated as soon as the patient can participate. For ear injuries, pillows are used to prevent chondritis and tissue adhering to the bed linens. Devices are fabricated to relieve pressure for an injured pinna.

Microstomia is a contracture of the oral aperture of the face (Fig. 43-15). It is associated with impaired oral hygiene, eating, and speech. In addition, microstomia may disrupt muscular and dental development in children (197). The contracture may involve the skin of the mouth or involve the perioral musculature that creates the sphincter of the mouth. The orbicularis oris muscle is separated from the surface by a thin subcutaneous layer and from the mucosa below by a thin submucosal layer.

Oral stretching splints are used to maintain the normal dimension of the mouth for those at risk of developing microstomia. These splints are often custom made and tailored to maximize comfort and benefit. Commercial devices are also available. Splint designs vary by direction of force (horizontal, vertical, or circumoral stretch) and orientation (intraoral or extraoral). Monitoring is required for skin irritation and breakdown. Factors to consider in prescribing a microstomia splint include age, dentition, stage of dental development in children, and location and depth of injury. Devices should be comfortable to wear, insert, and clean. Compliance is often challenging. To maximize success and achieve optimal patient compliance, a graduated wearing schedule is advised and more than one device is indicated (198,199).

The timing of initiating pressure therapy in clinical practice for facial burns is variable (200). Pressure is an accepted treatment for facial burn scarring and deformity. Face masks or pressure garments fitted to the face are widely used. In 1979, Rivers et al. (201) first described the fabrication of a transparent face mask for application of pressure to prevent scarring. Transparent rigid face mask is the most common (196) facial pressure device (Fig. 43-16). There is better patient compliance and social acceptance of a transparent face mask than a fabric face garment (202,203). Accuracy of fit is critical to successful scar suppression. The transparent face

**FIGURE 43-16.** Transparent face mask with magnets to secure eye glasses. (Compliments of Alicia J. Davis, C.P.O.)

mask allows for better fit, as one can easily monitor for scar blanching (201). Allely et al. described the use of laser Doppler imaging for mask fabrication. This technique holds the potential for increased precision and efficiency in fabricating transparent face masks (204).

There exists concern that pressure will alter the dental, maxillary, and mandibular features of a child. Some recommend the involvement of an orthodontist in all children with facial burns (205,206). Literature review reveals limited support for the effects of pressure therapy on preservation of craniofacial features after facial burns. In a literature review on the topic, investigators were unable to draw any conclusions because of a lack of statistically robust data (207). One study met inclusion criteria and included six children, three with total face masks and three with partial face masks of the lower face. Those with the lower face mask exhibited anterior protrusion of the teeth and little reduction in the inferior growth of the mandible. These changes persisted after pressure therapy was discontinued. For subjects with full face masks, maxillary horizontal growth was more affected than vertical growth. Radiographs in both groups after pressure therapy was discontinued demonstrated resolution in the bony abnormalities (96,205).

## CONCLUSION

With more patients surviving burn injuries, care is increasingly focused on the complications, rehabilitation, and long-term outcomes of burn survivors. Burn injuries may present as major catastrophic injuries, with a complex array of problems that include contractures, hypertrophic scarring, pain, neuropathy, and psychosocial problems. Physiatry is an integral component of the specialized multidisciplinary burn care team throughout the continuum of care. Rehabilitation interventions begin immediately after injury in the intensive care unit aimed at preventing long-term complications of burns. Splinting, positioning, and exercise are hallmarks of early rehabilitation. Burn care may continue for years after hospital discharge, managing physical and psychosocial impairments after burn injury and ultimately promoting maximal reintegration into the community.

# Rehabilitation for Patients with Cancer Diagnoses

## GENERAL ASPECTS OF REHABILITATION FOR CANCER PATIENTS

### Historical Background

Patients with cancer diagnoses are living longer because of a combination of early detection, a broader selection of cancer treatment options, and better general medical management. While the treatment of cancer has moved toward less invasive and more preservation-oriented techniques, there remains a high incidence of disability in individuals with cancer and survivors (1–3). Census data indicates cancer as the 13th most common cause of self-reported disability (4).

### Rehabilitation Expectations in the Cancer Population

While rehabilitation goals for cancer patients have historically been organized into restorative, supportive, preventative, and palliative categories (5), another important concept is that the clinical course can be both chronic and dynamic (6), resulting in need for rehabilitation at various points in the disease trajectory. The heterogeneity of cancer types creates very diverse rehabilitation needs in this population. The more common issues are highlighted here.

### Demographics of Cancer and Its Relevance to Rehabilitation

Cancer is the second leading cause of death in the United States, accounting for approximately one in every four deaths among both children and adults (7). Nearly 60% of all cancers occur in individuals age 65 and older, and age-adjusted incidence is ten times greater in individuals over age 65 than younger age groups (8). The overall 5-year relative survival rate for 1996 to 2002 was 66% (Table 44-1), up from 51% in 1975 to 1977, and 35% in the 1950s (9). Five-year survival for childhood cancers has improved from less than 50% prior to the 1970s to about 80% today, though there is variability by site (7). The lifetime risk of being diagnosed with cancer is approximately 40%, and there are greater than 10.7 million individuals alive in the United States with a history of cancer diagnosis (2004 estimate) (9).

Historically, knowledge of survival statistics has been important for rehabilitation decision making, because aggressive

restorative services may not be appropriate for those with a markedly reduced life expectancy. However, survival often varies markedly within a given tumor type because of factors such as stage of disease and histology, so each case must be approached individually. Radically improved survival rates now compel rehabilitation professionals to examine the needs of long-term survivors. Of particular interest are the more common cancers with large survivorship populations, such as breast and prostate cancer (7), and cancers known to have a high incidence of disabling complications (see next section) (10). Since cancer is most common in older age groups, the impact of cancer within the geriatric population is receiving increasing attention. In general, cancer in the elderly may not be more disabling than other common medical conditions such as diabetes or congestive heart failure (11), but more severe symptoms or extensive treatment is associated with greater loss of function (12).

## CANCER REHABILITATION SERVICE DELIVERY

One seminal study of the rehabilitation needs of individuals with cancer identified that 54% had physical medicine problems (10), with very high incidence (70% or greater) among those with central nervous system (CNS), breast, lung, or head and neck tumors. There was a large gap between the identified rehabilitation needs and the services actually delivered, which improved dramatically with a program for patient education, automatic screening of patients for rehabilitation needs, and introducing a physiatrist into the clinical oncology team. Organized cancer rehabilitation programs, while not widespread, have been described (13). Core components include a committed administration, physiatrist as medical director, and effective marketing, as well as practical considerations including accessibility.

Because of the heterogeneity of rehabilitation needs across the cancer spectrum, as well as the complexity of care in individual cases, screening and surveillance tools should be employed which are both systematic and clinically practical. Issues may be present at symptom, impairment and function levels. Visual analog scores have been described for pain, fatigue, appetite, mood, and sleep (14). Office-based tests that have been applied

to assess impairments and basic function include manual muscle testing, grip dynamometry, range of motion, limb girths, up and go test (15), timed walking, single foot balance, tandem walking (16), modified sit-and-reach test (for flexibility), and stand and sit test (for strength) (17). Karnofsky (Table 44-2) and Eastern Cooperative Oncology Group (ECOG) scales have been employed by oncologists as a measure of performance status, less so for functional outcome; hence, these measures are of uncertain value in rehabilitation. Some questionnaire-based tools developed for oncology patients incorporate both functional and quality-of-life measures. Examples include the Functional Assessment of Cancer Therapy (FACT), European Organization for Research and Treatment of Cancer Quality of Life Questionnaire (EORTCQ), Cancer Rehabilitation Evaluation System (CARES), and Functional Living Index-

Cancer (FLIC). The 36-Item Short Form Health Survey (SF-36), a health status instrument, has also been applied to the cancer population (18–20).

### Inpatient Rehabilitation

Several studies have shown that cancer patients and noncancer patients achieve comparable functional gains from inpatient rehabilitation programs, as measured by the Functional Independence Measure (FIM). Patients with neoplastic spinal cord injury (SCI) (21) and brain tumors (22,23) have been shown to have shorter rehabilitation lengths of stay but similar discharge rates to home when compared to age matched controls. Reasons may include higher initial FIM score (seen in some studies), and possibly fewer behavioral sequelae, better social support, and expedited discharge planning due to poor long-term prognosis in some cases (24). Functional improvements made during acute rehabilitation are maintained 3 months after discharge (25). Chemotherapy, radiation therapy, and specific tumor type have not been shown to adversely affect rehabilitation outcome (26,29).

The incidence of transfer back to acute care from rehabilitation is higher than noncancer patients in most (26–28) but not all (29) series. One study that examined reasons for transfer found that infection was more common in cancer patients than in controls (28). Low albumin, elevated creatinine, and use of feeding tube or indwelling bladder catheter have been reported to be risk factors for transfer (30). Prognosis and the patient's general tolerance of rehabilitation therapies must be weighed in the decision for inpatient rehabilitation. However, poor expected long-term survival is not a contraindication if substantial functional gains are likely to be made in the short or intermediate term. Functional gains for patients with advanced disease should be defined broadly enough to include family/caregiver training that will allow terminally ill patients to remain home with hospice services if that is their choice.

### Outpatient Rehabilitation

Outpatient care, typically, addresses specific musculoskeletal or soft-tissue problems, such as lymphedema, contracture, and pain, as well as mobility and self-care issues. Often there is need

**TABLE 44.2** Karnofsky Scale

#### Able to carry on normal activity; no special care is needed.

10 Normal; no complaints, no evidence of disease

9 Able to carry on normal activity; minor signs or symptoms of disease

8 Normal activity with effort; some signs or symptoms of disease

#### Unable to work; able to live at home; cares for most personal needs; varying amounts of assistance is needed.

7 Cares for self; unable to carry on normal activity or do active work

6 Requires occasional assistance, but is able to care for most of own needs

5 Requires considerable assistance and frequent medical care

#### Unable to care for self; requires equivalent of institutional or hospital care; disease may be progressing rapidly.

4 Disabled; requires special care and assistance

3 Severely disabled; hospitalization is indicated, although death is not imminent

2 Very sick; hospitalization necessary; active supportive treatment necessary

1 Moribund, fatal process progressing rapidly

0 Dead

for surveillance of symptoms and function, both at critical points in care (e.g., in association with surgery) and over an extended period of time. One study of individuals with advanced breast cancer and remediable disabling impairments found that outpatients were markedly less likely than inpatients to receive rehabilitation services (31). This suggests the need for improved rehabilitation systems for outpatients and perhaps especially for those with advanced disease. Home health care may be needed if mobility is a significant obstacle to treatment.

Increasing attention is being paid to appropriate models for outpatient care, especially survivorship care. The Institute of Medicine has recommended that all cancer patients receive a care plan at the end of treatment summarizing care and also detailing future concerns. While many of the issues such as surveillance for recurrence or new cancers, medical late effects, reproductive issues, genetic testing, and economic factors, are beyond the typical rehabilitation scope, other surveillance issues may be highly relevant for good functional outcomes and clearly do pertain to rehabilitation care. For example, some physical impairments, such as contracture or lymphedema, can occur as late effects that warrant ongoing physiatrist's assessment and management. In addition, the beneficial effects of physical activity are becoming increasingly convincing, both for cancer survival and reducing disability from comorbidities (32). The clinical focus and program structure of rehabilitation services for survivors vary widely but they tend to be most readily found, either as part of a comprehensive multidisciplinary outpatient cancer clinic or through referrals for outpatient consultations by physiatrists specializing in cancer care (33).

### Consultation During Acute Care

In the acute care setting, consultation is most frequently requested for evaluation and treatment of mobility and self-care needs, as well as for the assessment of cognitive status, communication, and swallowing. The physiatrist will be asked to participate in decision making about the setting for future rehabilitation efforts. Services for pain control or the provision of orthotic/prosthetic devices may also be indicated. One study administering the FIM instrument to acute oncology inpatients found that 87% of patients had rehabilitation needs on admission and 84% still had needs upon discharge (16). Another study applying organized interdisciplinary rehabilitation care to oncology inpatients reported significant functional improvement per Barthel Mobility Index and Karnofsky Performance Scale (34).

### Precautions

The physiatrist should routinely check for the following conditions, some a result of treatment such as chemotherapy, which empirically have an impact on the ability of the patient to safely tolerate some rehabilitation services, such as exercise or therapeutic heat.

1. Hematologic profile: hemoglobin less than 7.5 g, platelets less than 20,000, white blood cell count less than 3,000
2. Metastatic bone disease (see the section "Bony Metastatic Disease")
3. Compression of a hollow viscous (bowel, bladder, or ureter), vessel, or spinal cord
4. Fluid accumulation in the pleura, pericardium, abdomen, or retroperitoneum associated with persistent pain, dyspnea, or problems with mobility
5. CNS depression or coma, or increased intracranial pressure
6. Hypokalemia/hyperkalemia, hyponatremia, or hypocalcemia/hypercalcemia
7. Orthostatic hypotension
8. Heart rate in excess of 110 beats/min or ventricular arrhythmia
9. Fever greater than 101°F

## CANCER-RELATED PAIN

### General Approach to Assessment and Treatment

An estimated 60% of patients with cancer experience pain, with 25% to 30% having severe pain (35). Presence of pain, as well as other symptoms such as fatigue and insomnia, is associated with decrease in functional status, particularly in elderly cancer patients (12).

The World Health Organization (WHO) analgesic ladder, which has been validated and is considered the cornerstone of cancer pain management, matches treatment to the pain intensity. The first line of treatment is the nonopioid analgesics (aspirin, acetaminophen, and nonsteroidal anti-inflammatories, etc.). If insufficient, an opioid (codeine, oxycodone, morphine, fentanyl, methadone, etc.) should be added. In addition to intensity, one must consider multiple other factors, including acuity (acute, crescendo, chronic), pathophysiology (somatic, visceral, neuropathic), and temporal (continuous, intermittent, breakthrough) (35,36). Visceral pain is typically poorly localized, cramping, or deep aching. Somatic pain is well localized to discrete anatomic areas, often sharp or stabbing, and neuropathic pain has a burning, tingling, or throbbing quality. While the WHO ladder remains fundamental, increasing attention is being paid to other treatments, such as early use of interventional procedures when clinical assessment suggests a high chance of success, not just when all other measures have failed. Medication regimens should be tailored to specific pathophysiologic pathways. For example, when pain is due to direct tumor spread, antitumor therapy is most likely to be effective. Edema or antibody-mediated neurologic compromise is often managed with corticosteroids, inflammatory pain with nonsteroidal anti-inflammatory medication or corticosteroids, and neuropathic pain with antidepressants, anticonvulsants, and topical preparations (36).

Pain intensity can be measured by numerical (1 to 10 rating), categorical (none, mild, moderate, severe), or pictorial (Wong-Baker FACES) methods (36). Historically, complete pain relief has been the goal, and even described as a "patient right," but there is increasing recognition that it may not

always be possible, and that in most cases 33% to 50% pain reduction is clinically meaningful (37). Factors associated with difficulty attaining adequate pain control include neuropathic quality, psychologic distress, history of addiction, and impaired cognition (35).

Patient wishes should be included in the treatment plan, and use of a pain diary can assist in optimizing treatment (37). Technological innovations such as an interactive computer program for education about pain and other symptoms have also been developed (38).

### Opioid Strategies

Opioid agents that are commonly prescribed in the setting of cancer include oxycodone, morphine, hydromorphone, and fentanyl (Table 44-3). Meperidine and propoxyphene should be avoided due to toxic metabolites that can lead to seizures or cardiac arrhythmias, especially in the setting of dehydration or renal dysfunction (36). Methadone may be desirable in the setting of renal failure; however, because of its high potential for interaction with other medications and marked individual

variation in pharmacokinetics, it should only be prescribed by physicians highly experienced with this drug (35). While oral administration predominates in most physiatriic settings, increasing options have become available including parenteral routes such as transdermal, epidural, and intrathecal administration (39). In general, dosing is advanced to the level at which pain is controlled or at which toxicities preclude higher dosing. Daily effective dose can be established with short-acting preparations, and then converted to longer-acting forms. There should be additional dosing available for breakthrough, intermittent, or incident pain (including that associated with rehabilitation therapies) consisting of the equivalent of a patient's 4 hours dosing needs, 25% to 50% of that dose, or 5% to 10% of the total daily opioid dose (35).

Management of side effects is crucial. An effective bowel program, including stool softeners and laxatives should be prescribed. Sedation is often transient, but if persisting greater than 1 week, measures such as caffeine intake or use of a stimulant such as methylphenidate can be helpful (36). However, in the setting of delirium, a neuroleptic may be necessary after other

**TABLE 44.3 Pharmacologic Management of Pain**

Analgesic	Route	Duration of Analgesic	Dosage	Side Effects
Aspirin	Oral	4–6 h	650 mg every 4 h	Gastritis, tinnitus
Acetaminophen	Oral	4–6 h	650 mg every 4 h	Hepatotoxicity
NSAIDs <sup>a</sup>	Oral	Varies by agent	Varies by agent	Gastritis
Tramadol	Oral	6–8 h	50–100 mg every 6 h	Sedation, nausea, constipation
Morphine <sup>b</sup>	Intravenous	1.5–2 h	2–10 mg	Sedation, respiratory depression, constipation, confusion, pruritus
	Epidural/intrathecal	Up to 24 h	5 mg	
	Oral	2–4 h	15–60 mg	
Delayed release MS Contin, Roxanol	Oral	8–12 h	15–60 mg	Sedation, respiratory depression, constipation, confusion, pruritus
Methadone	Oral	24 h	Varies	Sedation, respiratory depression, constipation, confusion; variable dosing efficacy
Oxycodone	Oral	3–6 h (standard)	5–10 mg every 4–6 h	Sedation, respiratory depression, constipation, confusion
		12 h (sustained release)		
Hydromorphone	Oral	2–4 h	7.5 mg	Sedation, respiratory depression, constipation, confusion
	Parenteral	2–4 h	1.5 mg	
	Rectal	6–8 h	3 mg	
Hydrocodone	Oral	3–5 h	30 mg	Sedation, respiratory depression, constipation (often more severe than with other opioids), confusion
Fentanyl	Transdermal	72 h	50 µg/h	Sedation, respiratory depression, constipation, confusion. Use transdermal form only in opioid tolerant patients, for breakthrough;
	Transmucosal (buccal)	4 h (variable)	200 µg	only for cancer patients

<sup>a</sup>NSAIDs, nonsteroidal anti-inflammatory drugs. Numerous options, including COX-2 inhibitors (rofecoxib, celecoxib) with reduced incidence of gastritis.

<sup>b</sup>Dosing of this agent and other opioids will be highly variable, depending on degree of opioid tolerance. Dosing can be advanced.

metabolic causes have been excluded. Myoclonus related to opioid use may respond to baclofen, benzodiazepines, dantrolene, or valproate (35). While tolerance of a particular opioid may develop, reduced cross tolerance between different agents makes rotation of opioid drugs an effective way of avoiding escalating dosage requirements and the resulting side effects (35).

### Nonpharmacologic Pain Management Approaches

Physical modalities such as cryotherapy, biofeedback, iontophoresis, transcutaneous electrical nerve stimulation, and massage are well tolerated and believed to be safe, though the latter two are not performed directly over areas with known tumor (39). Deep heat such as ultrasound is contraindicated directly over an area of tumor. Data are limited, but one study in mice showed increase in tumor size (but no increase in rate of metastasis) with application of ultrasound (40). Routine physiatric procedures such as trigger point injections may be helpful. Psychologic techniques including imagery, distraction training, relaxation techniques, and coping strategies are encouraged (36). Interventional options can include nerve blocks, vertebroplasty, spinal analgesia (including long-term catheter systems), dorsal column stimulators, and neuroablative procedures (neurectomy, rhizotomy, cordotomy). Complementary and alternative medicine strategies are widely used, with increasing acceptance of massage and acupuncture, especially when other modalities have failed to achieve adequate pain relief (39).

## BONY METASTATIC DISEASE

Metastatic disease to the skeleton is one of the most problematic situations for clinicians managing musculoskeletal disorders. The skeleton is the third most common location for systemic metastatic disease (41) (Fig. 44-1). Breast, lung, prostate, kidney, and thyroid cancers account for 80% of

**FIGURE 44-1.** Extensive lumbar spinal metastasis, mixed lytic, and blastic lesions.

malignancies to bone (42). The biology of bone metastasis is thought to involve the interaction of cellular adhesion molecules with the architecture and circulatory supply of the bony apparatus (43). Bone metastases are osteolytic (primarily osteoclastic activity), osteoblastic (primarily osteoblastic activity), or mixed (43). Lymphoma, multiple myeloma, thyroid and renal cell malignancies have the highest rates of osteoclastic activity and therefore high levels of structural damage to bone and fracture risk. However, even in conditions where osteoblastic changes predominate, such as prostate cancer, pathologic fractures can occur. Early and aggressive management is imperative in maintaining function (44).

Pain is the most common clinical presentation of bone metastases (45). The pain is insidious, unrelenting, not associated with trauma or activity, and may be present or intensify at rest (46). The pain is frequently located in less common locations such as the thoracic spine or femoral shaft. Although pain is a common presentation, more than 25% of bone metastases are asymptomatic and found on routine imaging. Classic findings on physical examination include weight loss, exquisite point tenderness over the involved bone, and possibly neurological impairment. Failure to respond to initial treatment and progressive symptoms are “red flags” that require further scrutiny (47).

The assessment of patients with suspected bone metastasis requires an efficient structured approach, including a detailed history and physical examination. Functional assessment and social history are imperative for establishing rehabilitation goals and the need for family support. Initial laboratory evaluation in those with suspected metastatic disease should include a complete blood count, serum protein electrophoresis, urinalysis, C-reactive protein, and a comprehensive metabolic panel including calcium and alkaline phosphatase (47). Plain radiographs, though inexpensive and easily accessible, have limited utility in identifying metastatic bone disease because greater than 50% of the cortex needs to be involved before metastatic disease will be identified (47). The most sensitive imaging study for the identification of bone metastases is the triple phase bone scan, as only 5% to 10% of cortical involvement is required to identify abnormalities (48). Bone scans identify osteoblastic activity in bone and therefore may produce normal results (false negatives) in patients with primarily osteolytic disease such as myeloma or lymphoma. In addition, bone scans have poor specificity. For those patients with localized bone pain, equivocal bone scans, or neurological impairment, magnetic resonance imaging (MRI) with gadolinium is the most appropriate test, particularly for suspected spinal lesions (49). The recent advent of PET scanning has helped to detect tumor activity in cases when the above imaging studies are equivocal or when the primary lesion is osteolytic (50). In some cases, biopsy may be indicated to guide treatment (46).

The median survival for patients with isolated bone disease from cancer of the breast, prostate, or from multiple myeloma is 21 to 33 months (51). During this time, the appropriate use of supportive measures to decrease morbidity and pain, and improve function should be employed. Multidisciplinary

management involves collaboration among physiatry, orthopedic surgery, medical and radiation oncology, with care goals that encompass systemic disease management, pain control, skeletal stabilization, and rehabilitation.

Systemic management options, usually prescribed by a medical oncologist, include chemotherapy, hormonal therapy, monoclonal antibodies, and anti-angiogenesis agents. The administration of bisphosphonates is usually initiated when bone metastases are first detected, although in some cases they may be administered prophylactically. Intravenous bisphosphonates decrease skeletal morbidity, fracture rate, and pain through the inhibition of osteoclastic activity and suspected modulation of local tumor activity (52,53). Radiation therapy, including direct beam and radiopharmaceutical options, frequently can be effective in decreasing local tumor burden and controlling pain (54).

Multimodal pain control begins with the management of systemic malignancy as described above. Nonsteroidal anti-inflammatory agents are employed to decrease periosteal bone reaction, and opioids are used for general pain control (48). In some cases, more aggressive interventional measures may be necessary.

Stabilization of the skeleton is imperative for pain control and function. No system for predicting stability of long bone has been universally accepted. Generally, the greater the amount of cortex involved with metastatic disease the greater the risk of fracture (55). Size criteria for pathologic fracture risk in lower limb long bone include lesions measuring more than 2.5 cm, involvement of more than 50% of the bony cortex, and the Mirels scoring system incorporating pain, size, location, and radiographic appearance (49) (Table 44-4). A recent study comparing various methods found only axial cortical involvement of greater than 30 mm and circumferential cortical involvement predictive of fracture; the former measure has the advantage of being accessible with x-rays alone (56). In practice, it is often difficult to gauge the size of bony lesions, especially lytic ones, which may be irregular, permeative, and difficult to distinguish from surrounding osteopenia. Apart from radiographic assessment, pain that increases with weight bearing may be an indication of an unstable bony structure (46), warranting

early surgical assessment. Fracture risk may actually increase during the first 6 to 8 weeks after radiation as a result of tumor necrosis and softening of bone. Therefore, surgical stabilization is typically done prior to radiation of unstable lesions.

In the spine, the stability of the bone and the presence of neurological impairment guide the assessment in Harrington's classification of vertebral metastases:

- I. No significant neurological involvement
- II. Involvement of bone without collapse or instability
- III. Major neurological impairment without significant bone involvement
- IV. Vertebral collapse without neurologic impairment
- V. Vertebral collapse with neurologic impairment

For class III to V involvement, surgical intervention is warranted (54). Surgical management of the unstable skeleton is very effective in reducing pain and increasing function. Harrington found good or excellent pain relief in 96% of long bone and 88% of spinal fractures (57), and improved function in 82% of spine stabilization cases (57). A recent advance has been the NOMS algorithm, incorporating neurologic (cord compression), oncologic (radiosensitive or not), mechanical (movement-related pain; fracture/subluxation >5 mm, or angulation >11 degrees with subluxation >3.5 mm), and systemic factors (medical risks of surgery) into decision-making for surgery (58). In refractory cases or nonsurgical candidates, bracing can be considered, but wearing tolerance remains a significant barrier.

The rehabilitation of patients with bone metastasis is based on protection, pain control, energy conservation, and maintenance of function. Protection and pain control can be obtained through the use of bracing, mobility aids, and activity precautions. Some patients with exclusively lower extremity disease may be able to maintain mobility with the use of a cane or walker. Those with more diffuse (including upper limb), or bilateral disease may require a wheelchair or power mobility. Neutral spine techniques preserve function and minimize pain in patients with spinal metastases. It is essential to assess the weight-bearing status of all limbs when prescribing assistive devices for patients with known or suspected bone metastases as bony metastases usually occur at multiple sites, with 20% of metastases present in the upper limbs, especially the humerus (49). Exercise prescriptions should focus on increasing strength, endurance, and function with minimal loading or torsion of the affected bone. A typical exercise program may include aquatic therapy, non-weight-bearing exercise such as cycling and isometric exercise for strength maintenance. Compensatory techniques can decrease the biomechanical load on affected bones and maximize function. These include the use of reachers for activities of daily living, neutral spine techniques, and a step-to-gait pattern when climbing stairs. When metastatic disease limits independence, family training and education are beneficial to reduce the risk of injury to both caregiver and patient, and to identify needs for durable medical equipment.

**TABLE 44.4 Fracture Risk (>8 Points High Risk)**

	Points Assigned		
	1	2	3
Anatomic site	Upper extremity	Lower extremity	Trochanter
Lesion type	Blastic	Blastic/lytic	Lytic
Lesion size	<1/3 diameter	>1/3, <2/3 diameter	>2/3 diameter
Intensity of pain	Mild	Moderate	Severe

## CANCER-RELATED FATIGUE (CRF)

Fatigue is a normal physiological response to exertion. It becomes pathological when it persists, occurs during routine activities, and does not respond to rest (59,60). Stringent clinical studies routinely find that the majority of cancer patients will meet criteria for CRF at more than one time during their disease continuum (61). High prevalence, impact on function and quality of life, and caregiver burden make the assessment and treatment of CRF a central goal of almost every cancer rehabilitation program (62,63).

Numerous fatigue assessment tools have been validated for oncology patients (64). Busy clinicians, however, may find it easiest to screen their patients using a mild/moderate/severe designation based on a 0 to 10 Likert type scale. Patients reporting fatigue intensity of 1 to 3 are considered as having mild CRF, 4 to 6 as moderate, and 7 to 10 as severe. The National Comprehensive Cancer Network (NCCN) recommends screening for fatigue at the time of diagnosis, consistently during treatment, and as part of the long-term follow-up care (65), even after the completion of successful oncologic treatment.

It is not yet clear whether CRF is a specific physiologic process or “a final common pathway to which many predisposing or etiologic factors contribute” (66,67). Nonetheless, clinical studies have been able to recognize specific factors that are consistently associated with CRF and are therefore thought to precipitate it or intensify its impact. The most common associated factors are pain, emotional distress, sleep disturbance, anemia, nutritional deficiencies, deconditioning, and medical comorbidities (65) (Table 44-5). Identification of lead factors guides the treatment process.

Successful management of CRF requires the coordinated collaboration between clinicians who can address etiologic factors affecting a specific patient. The NCCN guidelines recommend four types of treatment interventions: (a) education and counseling, (b) general strategies, (c) nonpharmacologic, and (d) pharmacologic (65). Since CRF affects patients throughout the cancer continuum, the NCCN provides guidelines for three types of patients: (a) patients on active treatment, (b) patients on long-term follow-up, and (c) patients at the end of life (65).

General education about the nature and management of CRF provides reassurance and leads to earlier recognition and mitigation of its effects. General strategies, as opposed to cause-specific interventions, are intended to minimize the impact and intensity of existing CRF after reversible causes have been addressed. Energy conservation strategies developed for cardiac and pulmonary patients are equally effective for patients with CRF (68). Beneficial interventions include strengthening and endurance programs, psychosocial interventions, nutritional management, and sleep optimization.

The prevalence of disrupted sleep among persons with cancer diagnoses makes it one of the most common and intuitively obvious factors in CRF (69). Many cognitive and behavioral strategies exist for promoting restorative night time

**TABLE 44.5 Interventions for Fatigue**

Strategy	Examples
Restore energy balance	Correct anemia Nutritional and vitamin supplementation Correct endocrine dysfunction (thyroid)
Medications	Stimulants (methylphenidate, d-amphetamine) Analgesics Antidepressants (bupropion, SSRIs, TCAs) Regulate sleep/wake Glucocorticoids Investigational—cytokine-targeted therapy (including NSAIDs)
Exercise	Aerobic exercise is best-studied form. Individualized Attention to precautions Cachectic patients may not tolerate.
Energy conservation	Education Adaptive equipment
Psychologic/coping	Recreational activities Relaxation techniques Support groups Spiritual supports, participation

SSRIs, selective serotonin reuptake inhibitors; TCAs, tricyclic antidepressant agents; NSAIDs, nonsteroidal anti-inflammatory drugs.

sleep and minimizing daytime sleepiness (69). Addressing the underlying anxiety and depression often improves sleep as does increasing physical activity. Sleep can also be addressed with judicious use of pharmacological agents.

Anemia is a common cause of CRF that responds to medical management. Blood transfusions may be useful for more rapid correction of profound anemia, particularly after tumor resection or myeloablative chemotherapy. Several large scale studies demonstrated the utility of erythropoietin for both increasing hemoglobin and reducing fatigue scores in patients with anemia associated with chemotherapy (70). However, the use of erythropoietin in cancer patients was reassessed in light of data concerning increased risk of thrombotic events in dialysis patients receiving erythropoietin (71). Some studies have also shown a decreased survival rate in cancer patients treated with erythropoietin that was not associated with thrombotic events (72). Recent data suggest that target hemoglobin levels of 12 g/dL can confer symptomatic benefit without increasing risk (65).

In addition to medical management of factors contributing to CRF, physicians may use a range of prescription medications to treat CRF directly. Psychostimulants such as methylphenidate and modafinil have been used to treat CRF but their efficacy has not been definitively established (73–76). Corticosteroids are used for numerous purposes in cancer patients and may modulate CRF (77).

Numerous studies have explored the safety and efficacy of exercise interventions for patients with CRF. A meta-analysis

identified the greatest statistically significant impact in studies limited to a specific disease population such as breast cancer with less effect demonstrated when patients with heterogeneous diagnoses were recruited (78). Even when exercise interventions do not directly reduce fatigue scores, they nonetheless play an important role in the management of CRF by stemming the cycle of deconditioning that occurs as patients with CRF reduce their activity.

Cancer patients should be screened by a physician prior to the prescription of a moderate intensity exercise program. Clinical literature supports the use of therapeutic exercise for CRF in patients with stage I to III disease but fewer guidelines exist for patients with advanced disease, particularly bony metastases. Walking has been the most frequently used mode of exercise in studies assessing the effect of physical activity on CRF although a recent investigation studied the effect of higher intensity training utilizing cycle ergometry (79). None of the studies reviewed reported any serious adverse events related to the prescribed exercise program. Strength training has been less well studied than aerobic exercise in oncology populations. One randomized prospective study of 155 men with prostate cancer receiving androgen deprivation therapy demonstrated significant reduction in fatigue as measured with the FACT-F scale after participation in a 12-week resistance exercise program (80).

Overall, moderate intensity aerobic exercise can help ameliorate CRF during and after treatment and minimize its effect on the overall function and quality of life. Strength training is beginning to show positive effects as well for fatigue management although there are fewer studies supporting its role. It is best if exercise interventions are prescribed and administered by clinicians who have experience with oncologic patients and are familiar with relevant precautions and contraindications. Exercise studies targeting CRF in populations with comorbidities as well as metastatic disease are needed to enable safe and effective exercise recommendations for these patients.

Effective management of CRF requires a holistic approach that is best achieved through an integrated, interdisciplinary team including physicians, oncology nurses, physical, occupational, and speech language therapists, nutritionists and psychologists. M.D. Anderson pioneered a dedicated fatigue clinic and demonstrated high rates of patient satisfaction as well as some clinical improvement (62). Less formal CRF programs have been established elsewhere and are easily integrated into physiatric practices with established access to interdisciplinary team members who have oncologic experience.

## EXERCISE FOR THE CANCER PATIENT

### General Aspects

Exercise studies performed in the cancer population have consistently substantiated gains in numerous parameters, including cardiopulmonary fitness, fatigue (see “Cancer-Related Fatigue” section), quality of life, depression, and anxiety (81–83). There may also be benefits of exercise on immune function, such as

improved natural killer cell activity, monocyte function, proportion of circulating granulocytes, and duration of neutropenia; however, the implications of these effects are not well delineated on a clinical level, and not all studies have shown immune effects of exercise (84). This section focuses on general exercise principles in the setting of cancer; activity recommendations related to specific impairments will be covered in the respective sections.

Of note, physical activity appears to exert a protective effect against the development of some types of cancers, most notably colon and breast cancers (85). Obesity has been associated with increased risk of death from cancer in both men and women, with one large prospective study estimating effect of overweight and obese status as accounting for 14% of cancer deaths in men and 20% of those in women, with the strongest associations seen in gastrointestinal, kidney, breast, prostate, gynecologic, and some hematologic malignancies (86). Cancer prevention recommendations developed by the American Cancer Society include at least 30 minutes of moderately vigorous physical activity on 5 or more days of the week for adults (preferably 45 to 60 minutes), and at least 60 minutes for children and adolescents (87). Physician recommendation to exercise has been shown to improve self-reported total exercise among newly diagnosed cancer survivors (88).

While exercise studies overall have best explored breast cancer and the aerobic form of exercise, wider evidence is beginning to emerge, among a range of cancer types, also with favorable outcomes (17,89,90). Among exercise forms, cycle ergometry is often favored, with its advantages of positioning options, and relative ease of use by individuals with balance or coordination deficits (91). Preferences for exercise programs have begun to be explored, with patients often expressing interest in home or fitness-center-based exercise, especially walking. However, at least one study suggests that a supervised program may be more likely to yield measurable gains in physical performance (92). Patients voice an openness to, and even preference for, technically based approaches for receiving information (internet or CD-ROM). Many perceive better readiness to start an exercise program after than during treatment (93,94).

Most hematologic parameters for exercise are empiric. The concern with exercise in the thrombocytopenic state lies in the potential for increased blood pressure, which occurs most dramatically with isometric exercise, to result in intracranial hemorrhage, and for high-impact activities to result in muscular or intra-articular hemorrhage. The risk of hemorrhage correlates with the platelet count, but is mitigated by other systemic factors. In a study of acute leukemia patients (95), grossly visible hemorrhage was rare with a platelet count greater than 20,000, and no intracranial hemorrhage occurred with a platelet count greater than 10,000. In general, unrestricted exercise can be pursued with platelet counts greater than about 30,000 to 50,000. Aerobic, but not resistive, activities can be considered with platelet counts greater than 10,000 to 20,000. Active therapy is not advocated with platelet counts less than 10,000.

### Exercise for Patients Undergoing Chemotherapy or Postchemotherapy

Cancer patients treated with cardiotoxic agents such as anthracyclines can sustain permanent cardiac damage that affects physical performance. Patients treated with significant doses of these agents ( $>100 \text{ mg/m}^2$ ) can have reduced exercise time, reduced maximal oxygen uptake, abnormal heart rate response, ST- and T-wave changes, and exercise-induced hypotension (96). However, exercise time, peak oxygen uptake, and ventilatory anaerobic threshold can still improve with an exercise program, due to peripheral adaptation, despite the fact that cardiac parameters, such as exercise heart rate and stroke volume do not increase (96). A controlled study of patients undergoing aerobic exercise (supervised daily, supine bicycle ergometry) during treatment found multiple benefits in the exercise group, including less decrement in performance per treadmill testing, less pain, decreased duration of neutropenia, and shorter hospitalization (97). A study of home-based unsupervised exercise among early-stage breast cancer patients who had completed treatment (about half with treatment including chemotherapy) found higher self-reported physical activity and 1-mile walk test performance than controls, but no difference in accelerometry or anthropomorphic measures (98). A supervised program among breast cancer patients, before and during treatment, focusing on both strength and aerobic training at 40% to 60% maximal twice weekly for 21 weeks, did result in improved lean body mass, reduced body fat, and improved strength per submaximal muscle endurance protocol (99). Another supervised program among breast cancer patients that had completed treatment, focusing on aerobic training three times a week for 15 weeks, found improved peak oxygen consumption in the exercise group but no significant anthropomorphic differences (100).

### Exercise for Patients Undergoing Bone Marrow Transplantation

Exercise programs have been developed for bone marrow transplant recipients to counteract the debility occurring with medical morbidity and prolonged hospitalization, as well as to address other factors such as depression and social isolation. Supine or sitting exercise is generally well tolerated, but standing exercise should be attempted at least for brief periods to minimize gastroc soleus tightness. Supine exercise may be most comfortably performed with the head of the bed slightly elevated. Exercise programs emphasize range of motion, aerobic activity, such as walking or cycle ergometry, light resistive activities such as bridging and use of light weights, and deep breathing to prevent atelectasis and pneumonia (101). In one program, referral to physical therapy is placed when the patient is isolated to the room, or when unable to ambulate approximately 200 ft three times a day (101). For those in isolation, use of a sanitized bedside stationary bicycle or in-bed pedocycle facilitates activity (101). In those with graft versus host disease (GVHD), skin erythema and rash may occur. Protective padding can prevent pain and skin irritation during exercise, especially over the soles of the feet. Attention should be paid

to strengthening, due to risk of steroid myopathy. Medications such as quinine, carbamazepine, or baclofen may be useful for cramping symptoms of GVHD (102). One study of treadmill training (interval pattern) 30 minutes daily for 6 weeks in bone marrow transplant recipients with stabilized platelet counts and clinical condition resulted in improved physical performance, measured by distance of treadmill walking (103). Another controlled study of stretching and treadmill training found improved preservation of strength, measured by dynamometer in multiple muscle groups among the exercise group at 6 weeks post-transplant (104).

### Cachexia

Endogenous tumor necrosis factor (TNF), or that administered exogenously as antineoplastic therapy, can reduce skeletal muscle protein stores. A low-to-moderate intensity of exercise, which relies mainly on type I muscle fibers, which are fatigue resistant, should be encouraged, reducing activity at the onset of fatigue. While evidence is limited, empirically, for individuals with marked cachexia, rehabilitation efforts should focus on energy conservation and methods other than strenuous exercise to achieve functional goals.

## NEUROLOGIC COMPLICATIONS OF CANCER

Neurological impairments have been identified in 30% to 46% of cancer patients (105). Neurological complications are the second most common reason for admission to the hospital, after admissions for routine chemotherapy (106). Patients present most commonly with low back pain, limb weakness, headaches, and mental status changes (105). Due to the high rate of associated disability and the vulnerability of the nervous system to reversible and irreversible damage, early identification and treatment can prolong life and diminish disability.

### Metastatic Brain Disease

Brain metastases are the most common catastrophic neurological impairment in the cancer population. The incidence of metastatic disease to the brain is ten times greater than the incidence of primary tumors (107). Brain metastases occur most frequently with lung, breast, colorectal, melanoma, and genitourinary cancers (105), with lung and breast malignancies accounting for 60% of all lesions. Approximately 85% of brain metastatic lesions are found in the cerebrum and 15% in the cerebellum (108). The most common presenting complaint is a progressive headache, often worse when recumbent. Hemiparesis, seizures, and mental status changes occur frequently. Evaluation includes a complete neurological and clinical examination to exclude other etiologies such as stroke and central nervous system (CNS) infection. Gadolinium-enhanced magnetic resonance imaging (MRI) is the gold standard. Management includes early treatment with corticosteroids to decrease brain edema, and anticonvulsants to decrease seizure risk. Excision of brain metastasis may be indicated, especially if the metastasis is single, the cancer is otherwise well

controlled, and the lesion(s) appears to be the major factor limiting survival or quality of life. Clinical trials have shown that in certain patients a combination of surgery and radiation therapy is superior to either treatment alone (108). Whole brain radiation, with standard doses of 3,000 cGy given over ten treatment sessions, as well as adjuvant chemotherapy are important components of treatment. Intrathecal methotrexate administered through a reservoir secured beneath the scalp has been used to treat CNS and leptomeningeal disease with mixed results but does avoid some of the more toxic side effects of systemic methotrexate. Prognosis for solitary brain lesions and those able to maintain ambulatory function is good. Prognosis is poorer for those with persistent headache, visual dysfunction, or ongoing mental status changes (109). See “Brain Tumor” section for discussion of specific rehabilitation approaches.

Leptomeningeal disease is a result of the spread of malignancy to cerebrospinal fluid (CSF). It is most commonly associated with breast cancer, small cell lung cancer, and melanoma (108). 75% to 80% of cases involve spine, 50% cranial nerves and greater than 50% brain (110). Leptomeningeal disease causes back pain, radiculopathies, cranial nerve dysfunction, and mental status changes. The diagnosis is made by MRI with gadolinium and/or CSF analysis. Treatment is with intrathecal chemotherapy or radiation. The prognosis is uniformly poor.

### Spinal Cord Involvement

Spinal cord compression due to metastatic disease occurs in 5% to 14% of all cancer patients (111). Twenty-five percent of patients with neoplastic spinal cord compression do not have a previous diagnosis of cancer (105). Metastases from prostate, breast, lung, and kidney primaries as well as multiple myeloma are the most common sources (112). The thoracic spine (70%) is the most frequent site of metastases followed by lumbar (20%) and cervical (10%). Metastases to the spine characteristically present as progressive, insidious back pain that is worse when recumbent along with associated neurological impairment (105,112). On average, patients have low back pain for 60 days before diagnosis (113). Clues to metastatic disease include a history of cancer, constitutional symptoms, thoracic level pain, and bowel or bladder dysfunction. Findings on physical examination may include point tenderness, paraparesis, a sensory level, and upper motor neuron findings (111). Motor abnormalities often precede sensory changes as a result of epidural extension preferentially affecting the anterior spinal cord, with recovery in the reverse order.

Early diagnosis is the key. Patients presenting without paresis have longer survival than those presenting with paresis (114). Corticosteroids (usually dexamethasone) are administered with a 100 mg loading dose, followed by 4 mg every 6-hours. Palliative radiation is indicated in those with metastatic disease and stable spinal structures.

When disease renders the spine unstable, surgical decompression and stabilization may be pursued for patients who are operative candidates. See “Bony Metastatic Disease” section, and “Rehabilitation of Spinal Cord Injury” of Chapter 27.

### Paraneoplastic Neuromuscular Disorders

Paraneoplastic neuromuscular disorders (PND) are a remote effect of cancer caused by antibody formation by the primary tumor (115). Neuromuscular disorders can precede the diagnosis of cancer by years. These disorders are rare, seen in only 0.01% of cancer patients (116). The most common tumor associated with PND is small cell lung cancer accounting for 50% to 75% of cases (116). While neuromuscular junction disorders will be the main focus of this section, various other paraneoplastic phenomena can occur, of which the physiatrist should be aware. These disorders include cerebellar degeneration, organic dementia, metabolic encephalopathy from electrolyte disturbance, proximal myopathies (as from carcinoid), and orthostasis from autonomic instability.

Lambert-Eaton myasthenic syndrome (LEMS) is found in 3% of patients with small cell lung cancer (116). The disorder results from presynaptic inhibition of calcium release at the neuromuscular junction. Proximal weakness, autonomic dysfunction, and improvement with exercise are common clinical findings. Diagnosis is established by electromyography and nerve conduction (EMG/NCS) studies. Myasthenia gravis (MG) is a postsynaptic neuromuscular junction disorder that is a result of autoimmune degradation of the postsynaptic membrane. MG is found in 15% of patients with a diagnosis of thymoma (116). The hallmarks of MG are ptosis, disconjugate gaze, fatigue on upward gaze, and proximal weakness worsened by activity. Electrodiagnostic studies, antibody analysis, and an anticholinesterase challenge are used to confirm diagnosis.

Paraneoplastic subacute neuropathies include sensory, sensorimotor, and demyelinating forms (115). The clinical presentation is that of rapid (days to weeks) onset of peripheral neuropathy affecting various fiber types. The sensory and sensorimotor involvement is most commonly associated with small cell lung cancer, whereas demyelinating processes are associated with lymphoma. Monoclonal paraproteins create neuropathies in multiple myeloma, osteosclerotic myeloma, Waldenström's macroglobulinemia, amyloidosis, and  $\gamma$ heavy-chain disease. Typically, the neuropathy is distal, mixed sensory and motor, with axonal loss and segmental demyelination. The management of PND includes treatment of the primary tumor and immune mediation (116).

### Polyneuropathy

Polyneuropathy can result from numerous factors in the cancer patient, including nutritional deficiencies, paraneoplastic disorders (as discussed above), and medical comorbidities. However, the most common cause is chemotherapy-induced polyneuropathy (CIP). Dose-dependent toxicity occurs in peripheral nerves and is commonly associated with a handful of agents (117) (Table 44-6). The pathophysiology of CIP includes disruption of axoplasmic microtubule transport, axonal “dying back,” and direct effects to the dorsal root ganglion (117). The sensory nerves are typically more affected because of the smaller fibers and the location of the dorsal root ganglion outside the blood-brain barrier. The onset of neuropathy coincides with the administration of chemotherapy, and should not progress after treatment has stopped.

**TABLE 44.6** Chemotherapy-Associated Polyneuropathies

Tumor	Agents	Trade Name	Nerve Fibers
Breast	Taxanes	Taxol/Taxotere	Sensory > motor
Lung	Taxanes	Taxol	Sensory > motor
	Platinum	Carboplatin	Pure sensory
		Cisplatin	Pure sensory
Ovarian	Platinum	Carboplatin	Pure sensory
		Cisplatin	Pure sensory
	Taxanes	Taxol	Sensory > motor
Myeloma	Thalidomides	Sensory > motor	
Lymphoma	Vinca alkaloids	Vincristine	Motor = sensory
Colon	Platinum	Oxiplatin	Pure sensory

Symptoms of dysesthesias, sensory loss, and allodynia typically begin in the foot and ascend. Motor weakness and autonomic dysfunction are delayed findings and may be a sign of significant toxicity. The differential diagnosis of CIP includes nutritional deficiencies, paraneoplastic disorders, mononeuropathies, radiculopathy, myelopathy, and brain disorders. Definitive diagnosis can be obtained through the use of electrodiagnostic studies. An accurate diagnosis of CIP is required to avoid unnecessary discontinuation of chemotherapy. The management of CIP includes alteration of dosing, and symptom management with medications (see “Cancer-Related Pain” section). Several agents have been evaluated as potential chemoprotective agents but none have proven beneficial (118). Rehabilitation principles include education, safety awareness, gait and proprioceptive training, and the prescription of orthoses and assistive devices for those with motor as well as sensory deficits.

## RADIATION-INDUCED TISSUE DAMAGE

Radiation therapy (RT) is commonly used for curative or palliative intent. For those tumors that are significantly radio-responsive (seminoma, head and neck cancers, and prostate cancer), it may be used as the sole treatment. In many cancers such as breast, colorectal, lung, lymphoma and melanoma, radiation is used in concert with surgical resection or chemotherapy. Systemic spread of cancer can be managed with palliative RT to reduce tumor burden, pain, fracture risk, and neurological impairment. RT is typically given via external beam, brachytherapy (local radioactive-implanted materials), or via stereotactic equipment (in certain brain tumors). The radiation is given in fractions (individual doses) over a set period of time (treatments). The overall effects of radiation are a result of individual dose, cumulative dose, and number of treatments (119). The recent advent of three-dimensional techniques, intensity modulated techniques, and brachytherapy have helped to localize the radiation to the tumor site and reduce surrounding soft-tissue effects (120). In addition, hyperfractionated regimens have helped to decrease acute complications from intense dosing.

The local effects of RT can lead to many complications (Table 44-7) (121). Soft-tissue restriction, swallowing dysfunction, and neurological impairments are the most commonly encountered issues for rehabilitation physicians. Swallowing dysfunction will be covered in the “Head and Neck Cancer” section. Soft-tissue fibrosis as a direct result of RT results in dermal fibrosis, musculotendinous contraction, and joint restriction with resulting loss of range of motion and function. The most commonly affected joints are the glenohumeral joint after axillary RT for breast cancer, the femoroacetabular joint after RT for cutaneous malignancies, and the neck after treatment for head and neck cancer. The loss of range of motion may start with guarding from painful, irradiated skin and is followed by contraction of the musculotendinous unit and joint fibrosis. Prevention through meticulous skin care, soft-tissue mobilization, and range of motion techniques is the primary means of management. The use of pentoxifylline may be beneficial to restore microvascular supply to the soft-tissue structures and thus help preserve mobility (119). The importance of delayed

**TABLE 44.7** Radiation Therapy Side Effects

Acute	Delayed
Fatigue	Soft-tissue fibrosis
Nausea	Skin atrophy
Vomiting	Auditory changes
Anorexia	Pulmonary fibrosis
Skin erythema	GI stricture
Desquamation	Thyroid dysfunction
Mucositis	Brain necrosis
Xerostomia	Myelitis
Taste loss	Plexopathy

effects of RT and the need to maintain a stretching regimen for life should be emphasized for patients. Patients with radiation-induced skin damage should wash gently with warm water and mild soap, and avoid sun exposure, rubbing (such as straps, belts, or collars), or chemical irritants (such as perfumes or deodorants) to the affected site. Mild cases may improve with emollients such as baby oil or other alcohol-free topical preparations, such as aloe or Aquaphor, whereas more severe cases might require a topical corticosteroid or specialized wound care preparations. Skin care recommendations should be made in conjunction with the practice of the radiation oncology team, especially during the period of ongoing radiation.

Neurological complications of radiation therapy include myelopathy, plexopathy, peripheral nerve injury, and encephalopathy. Long-term neuropsychologic sequelae have been reported even after low dose whole brain RT, especially in children. Restrictive dosing regimens and hyperfractionation have significantly decreased the rates of neurological impairment secondary to RT. Myelopathy is typically seen with cumulative doses greater than 5,000 Gy. The symptoms consist of sensory abnormalities, Brown-Séquard syndrome, followed by ascending weakness to the site of RT. The onset is greater than 12 months after completion of RT and the work-up should exclude possible reversible causes of myelopathy (121). Treatment is primarily supportive.

Radiation-induced plexopathy is usually seen in the upper trunk of the brachial plexus, and in the lumbosacral plexus. The clinical presentation is that of painless weakness with insidious progression that may even result in pan-plexopathy (122). Brachial plexopathy is rarely seen today secondary to smaller fractions and lower cumulative doses but had a high association in breast cancer patients receiving fractions of greater than 2.2 Gy and cumulative doses greater than 44 Gy (123). Plexopathy is usually diagnosed via MRI, revealing fibrosis of the plexus; electrodiagnostic studies may reveal the pathognomonic myokymic potentials.

Peripheral nerve injury secondary to RT is a rare occurrence, primarily occurring with cumulative doses greater than 6,000 Gy (121). Focal nerve injury results in painless weakness and may also be associated with myokymic discharges on electrodiagnostic studies (121).

Unwanted side effects of intracranial radiation are conventionally divided into *acute* (1 to 3 months), *early-delayed* (3 to 12 months), and *late-delayed*. There is limited risk of acute injury using contemporary protocols but coadministration of methotrexate or anticonvulsants may precipitate acute encephalopathies or toxic epidermal necrolysis that mandate inpatient hospitalization. Acute radiation encephalopathy is typically seen with single doses greater than 300 Gy, is related to increased intracranial pressure, and is self-limiting (121). In addition to *acute effects*, *early delayed effects* after whole brain RT include neurologic deterioration with somnolence, headaches, and worsening of focal symptoms that may resolve over the following months. Comprehensive imaging, clinical, and laboratory evaluation are needed to distinguish this condition from tumor recurrence or infection. The mechanisms of the *late delayed effects of radiation*, specifically radiation necrosis

and cerebral atrophy are poorly understood. Necrosis is often difficult to distinguish from recurrence and may require evaluation by PET scan. Late radiation necrosis occurs in 3% to 5% of patients receiving greater than 5,000 Gy and usually begins 1 to 2 years after completion of RT (121). Management is with corticosteroids or resection. Late radiation changes secondary to atrophy present with ataxia, dementia, and incontinence usually 1 year or more after whole brain irradiation of greater than 3,000 cGy. Treatment is supportive.

## LYMPHEDEMA

The lymphatic system is a component of the circulatory system designed to mobilize cellular debris, metabolic byproducts, and infectious material (124). The objective is to transport these particles to local and regional lymph nodes for degradation and to return the fluid to the central vasculature. The peripheral lymphatic system is divided into superficial and deep lymphatics (124). The superficial lymphatics are web-like and course directly under the skin. The deeper lymphatics run alongside the vascular system. The lymphatic system mobilizes fluid slowly via muscle contraction and respiration toward the centrally located lymph nodes in the groin and axilla. After lymph node processing, the fluid drains into the lymphatic ducts and central vasculature.

Lymphedema is a disorder of lymphatic fluid accumulation resulting in swelling, typically in an extremity but it may also involve the face, thorax, or abdomen. The most common malignancies associated with lymphedema include breast, melanoma, gynecological malignancies, and lymphoma. The first three disorders are associated with lymphedema, primarily because staging and treatment of these malignancies includes lymph node dissection. In breast cancer, a full axillary dissection typically involves removal of lymph nodes below the axillary vein, whereas in melanoma all regional lymph nodes below the clavicle are removed (124). Sentinel lymph node dissection, which includes sampling of lymph nodes that drain directly from the site of the tumor, leads to smaller numbers of lymph nodes being removed and reduces but does not eliminate risk of lymphedema (125,126). Lymphoma is associated with lymphedema secondary to direct invasion of lymph nodes. The risk of lymphedema approaches 25% in breast cancer patients. Associated risk factors include axillary lymph node dissection (ALND), metastatic involvement of lymph nodes, radiation therapy, obesity, and increasing age (127).

Lymphedema usually presents as painless, gradual, colorless swelling with heaviness and loss of limb contour. For patients presenting with rapid onset of swelling, with pain or erythema, one must exclude metastatic seeding (malignant lymphedema), infection, and thromboembolic disease. Two types of presentation are seen in patients with lymphedema. The first type has a gradual onset of fluid accumulation after lymph node removal secondary to overload of the lymphatic system with normal daily fluid production (normal output lymphedema). The second presentation consists of an acute increase in lymphatic fluid that overwhelms the compromised system (high output lymphedema). Common causes of high

**TABLE 44.8** Factors Promoting Increased Lymphatic Fluid Production and Prevention Strategies

Factor	Example	Prevention
Infection	Cellulitis, lymphangitis	Prevent breaks in skin Avoid venipuncture Gloves during high-risk activities
Lymphatic constriction	Tourniquets Tight clothes Scar tissue	Avoid blood pressure cuffs Blood draws in opposite arm Scar tissue mobilization
Increased metabolism	Burns/extremes of heat	Avoid hot tubs/sauna Sun screen
Anaerobic metabolism	Excessive exercise	Avoid fatigue and soreness with exercise; build exercise routine gradually
Trauma	Fractures, surgery	Protection, compression garment
Air travel	Low ambient air pressure	Compression garment

output lymphedema include cellulitis, lymphangitis, trauma, thermal burns, and increased metabolism in the at-risk limb (Table 44-8). Lymphedema progresses in stages. The first stage is a primarily fluid stage in which arm volumes diminish with elevation and use of external compression. As lymphatic fluid accumulates in the extremity, an inflammatory reaction ensues that results in subcutaneous fibrosis and hardening of tissue. This is considered the hallmark for stage two lymphedema. Stage two lymphedema does not resolve with elevation and compression garments. Stage three lymphedema is identified by cutaneous fibrosis and verrucous hyperplastic changes of the skin and is rarely seen in the upper extremity (124). As lymphedema progresses, pain may develop secondary to constriction of underlying soft-tissue structures and overload of the supporting structures such as the shoulder (128) (Fig. 44-2).

**FIGURE 44-2.** Kinesiotaping, an emerging modality for lymphedema, and has shown favorable patient tolerance. Tsai H-J, et al. *Support Care Cancer*. 2009;17(11):1353–1360.

The clinical evaluation of lymphedema should include a history of the primary malignancy and the aspects of treatment that have impacted the lymphatic system. The onset, duration, and progression of lymphatic swelling should be identified. In addition, identifying attempted management methods is important. Functional restrictions related to lymphedema (loss of shoulder or hand function) should be identified. Full musculoskeletal and neurological examination is needed to identify any underlying deficits. The skin examination should include general skin and soft tissue characteristics, and a specific focus on surgical and irradiated sites. In addition, identification of cellulitis or lymphangitis is paramount to halt processes that may lead to worsening lymphedema. The lymphatic evaluation includes palpation of all lymphatic territories. Examination should include limb girth measurements, usually performed via tape measure or volumetric displacement of the affected and contralateral extremities (129). Suspicion for recurrent malignant disease, while often unlikely to occur, should be part of care.

The management of lymphedema is performed to reduce symptoms, preserve cosmesis, maintain function, and decrease risk of recurrent infection. Complex decongestive therapy (CDT) is the most effective treatment (130). One component of CDT consists of manual lymphatic drainage, which is a massage technique promoting proximal lymph decongestion by fluid mobilization toward unaffected lymphatic territories. Skin care to reduce risk of infection is important and should be combined with stretching and soft-tissue mobilization techniques to the proximal limb, helping to reduce stasis of the lymphatic system. Wrapping the extremity with short stretch bandages to promote lymphatic flow out of the limb is the next phase and can be augmented by use of high tensile foam to break up fibrosis. The final phase uses exercises with gentle compressive wrapping in place in order to use the physiological muscle pump to propel fluid to the proximal lymphatics. CDT is typically divided into a decongestive phase that consists of 24 hours per day compression usually under the guidance of a trained physical or occupational therapist, and

a maintenance phase consisting of wrapping at night (performed by the patient or caregiver) and compressive garments during the day. In the maintenance phase, regular surveillance by a physician should be performed to assure volume reduction is maintained. Pneumatic pumps are also available but are controversial. They may be helpful in situations where the above treatments are not clinically feasible, or response is poor. Pneumatic pump use requires a time-consuming daily routine, and clinical response may be modest (129,130).

Evidence confirming the importance of early detection is emerging. A recent case series employing pre- and postoperative volumetric measurements via optoelectric perometry demonstrated subclinical lymphedema in 49% of ALND patients. Early treatment with provision of a 30/20 mm Hg compression sleeve and gauntlet was effective in reducing limb volume to near baseline levels (131).

Malignant lymphedema, resulting from spread of cancer into remaining lymphatics, presents with rapid swelling and a mottled appearance of the skin in the affected limb. Clinical examination may also reveal lymph node fullness. Evaluation should include exclusion of thromboembolic disease and imaging of the regional lymphatics with computed tomography (CT) or MRI. Identifying locoregional recurrence is imperative to initiate early treatment to reduce functional loss and maximize life expectancy. The primary treatment is management of the occluding tumor.

## IMPACT OF CANCER AND CANCER TREATMENTS ON NUTRITION

Nutrition is an essential variable for all rehabilitation outcomes but specific concerns apply to cancer patients at different points during the disease continuum. Many cancers as well as oncologic treatments affect nutritional status resulting in delayed wound healing, longer hospital stays, diminished quality of life, lower survival rates, and reduced functional performance (132,133).

Guo et al. recently demonstrated a 50% prevalence of below normal prealbumin (<18 mg/dL) in cancer patients admitted to an inpatient rehabilitation unit (134). Older studies found that close to two thirds of cancer patients developed inanition during the course of their disease, demonstrating severe risk in the absence of systematic intervention (135). Multiple anthropometric and laboratory measures can be used to elegantly characterize malnutrition in individual cancer patients but serum albumin below 3 g/dL and loss of 10% or more of stable pre-illness body weight continue to be the most reliable indicators of malnutrition in clinical practice. Laboratory and radiographic studies are necessary for identifying and responding to reversible components of malnutrition in cancer patients. Folate or B12 deficiencies may precipitate symptomatic anemia while hypercalcemia may induce anorexia and nausea. The Bristol-Myers Anorexia/Cachexia Instrument and the Functional Assessment of Anorexia/Cachexia Therapy provide validated means for assessing the impact of malnutrition

on patients and can be used sequentially to track the effects of prescribed interventions (136).

Weight loss and malnutrition in cancer patients occur as the result of primary and secondary processes. Secondary processes that interfere with intake and absorption are common and more easily reversible. Nausea and anorexia may be associated with specific chemotherapy regimens as well as with malignancies involving the gastrointestinal system. Depression may be a cause of reduced intake. Patients with head and neck cancers and other diagnoses frequently present with or develop significant dysphagia. Others develop mucositis as the result of treatment regimens. Radiation enteritis can cause malabsorption, intestinal obstruction, and even fistulas that may require total bowel rest and parenteral nutrition.

Secondary causes of malnutrition in cancer patients should be identified proactively and tailored treatment plans should be introduced as early as possible. Mucositis can be treated with ice chips and oral analgesics although these may decrease enjoyment of food. Avoiding anticholinergic medication and adding oral rinses or pilocarpine to promote salivary flow can limit the effect of dry mouth on oral intake. Oral supplements may be more easily tolerated and appreciated than solid foods. Modifications can be made to minimize the effect of acquired aversions such as the use of plastic utensils for patients complaining of a metallic taste or the elimination of odors that affect smell-sensitive patients. Antiemetics such as ondansetron, prochlorperazine, and trimethobenzamide can be used to mitigate nausea while prokinetic agents such as metoclopramide can reduce early satiety from gastric stasis. Appetite stimulants including megestrol acetate and drobinol are widely used and have been shown to increase intake and promote weight gain (137). It remains unclear, however, whether these gains reflect the actual increase in fat-free mass (FFM) needed for improved function. Concern over the prothrombotic effect of megestrol acetate has led to successful trials with lower dosages (138). Anabolic steroids such as oxandralone may be used to promote lean body mass in patients with androgen receptor negative malignancies (139).

Extreme weight loss, specifically the loss of lean body mass, may be a primary disease-related process. Cancer cachexia was previously thought to result from direct tumor effect but more recent investigations have suggested that cytokine-mediated processes alter the overall metabolic balance in cancer patients and animal models. TNF, proteolysis inducing factor (PIF), and interleukin 6(IL-6) dependent mechanisms shift metabolic processes increasing lipolysis, protein consumption, and energy expenditure (140).

Timely nutritional assessment and intervention are essential to effective cancer rehabilitation. Identifying nutritionists with oncologic experience can be invaluable for cancer rehabilitation programs. The American Dietetic Association has published standards of practice and professional performance for specialty accreditation in the area of nutritional management of oncology patients (141). In addition to early assessment and monitoring the impact of nutritional interventions, nutritionists in many cancer programs serve as a de facto clearing house

for patient use of complementary medicine and nutraceuticals—topics that patients are often uncomfortable discussing with their physicians. A growing body of literature endorses the addition of immunomodulating nutrients, specifically *n*-3 polyunsaturated fatty acids (eicosapentanoic acid, docosahexanoic acid), arginine, and nucleotides (142). Other patients may have concerns about whether specific food groups may promote tumor growth or interfere with treatment. Previously, restrictive neutrapenic diets were used during chemotherapy but are no longer promoted in areas where the general food supply is relatively well monitored for infectious agents. Nutritionists often work one-to-one with patients and their families but can also contribute through organized support groups, addressing shared concerns such as weight gain during and after treatment for breast cancer, care provider responses to dysphagia, or healthy eating habits for long-term survivors.

## CANCER-RELATED SEXUAL DYSFUNCTION

Sexual dysfunction may occur as a primary effect of malignancy but more commonly occurs as a side effect of treatment. Sexual function can be affected by disturbance at many levels, including psychologic, central or peripheral nervous system, endocrine, pelvic, vascular, and local effects on gonadal structures. Physical changes may interfere with the patient's concept of his or her sexual attractiveness. Depression may result in low sexual drive. Sexual dysfunction in cancer patients may persist long after treatment is completed, and it is important for the practitioner to inquire about it (143).

In men, chemotherapy can have adverse effects on spermatogenesis and also on testosterone production. Neuropathies, including dysautonomia, can interfere with the emission phase of male orgasm. Endocrine effects occur in men with prostate cancer treated with orchiectomy or with hormonal regimens to reduce serum testosterone. In women, gonadal toxicity can also occur with chemotherapy, especially alkylating agents, and permanent menopause may occur with combination chemotherapy.

Radiation therapy to the prostate or testicles can produce erectile dysfunction, possibly as a result of acceleration of pre-existing atherosclerosis from postradiation fibrotic changes. In women, radiation therapy to the pelvis produces premature menopause, with a dose of as low as 600 to 1,000 rad permanently destroying ovarian function. Radiation also produces damage to the vaginal epithelium, and the fibrotic process can continue over years. The result can be dyspareunia, postcoital bleeding, and even vaginal ulcers. After local radiation therapy for cervical cancer, stenosis of the upper vagina can occur.

After prostate surgery, reports of erectile dysfunction have varied widely, from 9% to 86%, probably related both to the extent of surgery (and other therapies) and assessment techniques (144). More rarely, urinary incontinence occurs. Similar problems may occur after radical cystectomy and abdominoperineal resection of gastrointestinal tumors.

First-line therapies for erectile dysfunction include education and counseling, oral medications (such as sildenafil,

ildenafil, or tadalafil), and the use of a vacuum device. Second-line therapies include use of intraurethral agents such as alprostadil, and intracavernous injection therapy (as with papaverine), and the third-line option is surgery for penile prosthesis. Following retropubic prostatectomy, higher doses of sildenafil may increase smooth-muscle content, with potential benefit of maintaining the proerectile ultrastructure during the recovery process (144).

Among breast cancer survivors, chemotherapy has been associated with greater reported sexual problems (145). Hormonal therapies, especially tamoxifen, may also produce side effects such as menstrual changes, vasomotor symptoms (hot flashes, headaches), and vaginal dryness (143).

Among women presenting to a sexual medicine clinic at a large cancer hospital, the most common problems were dyspareunia (72%) and vulvovaginal atrophy (65%). The most common interventions included vaginal moisturizers and water-based lubricants (89%), psychosexual counseling (46%), and local, minimally absorbed vaginal tablets (35%), with 70% of those attending follow-up sessions reporting improvement (146). In general, greasy lubricants, such as petroleum jelly, should be avoided because they may block the urethral opening. Counseling is usually short term and optimally includes both partners. Disease or treatment-specific effects on sexual function should be discussed with the patient, including the use of drawings or diagrams when appropriate. For women who have undergone resection of pelvic tumors, vaginal dilators or pelvic floor exercises may also be indicated. Preservation of fertility is an increasing focus in many programs.

Patients should be encouraged to maintain a good personal image as well as physical closeness and intimacy. The American Cancer Society's *Look Good, Feel Better and Reach to Recovery* programs can be very helpful. Peer support through ostomy groups can be of benefit.

## RETURN TO WORK AFTER CANCER

Return to work after cancer is usually favorable. However, a large study exploring employment status of cancer survivors who had been working at the time of diagnosis, found 20% reporting disabilities, and about 13% had stopped working for cancer-related reasons, mostly after the first year. Diagnoses most likely to affect long-term employment status include CNS tumors, head and neck cancers, and advanced hematologic malignancies (147). Data from the Childhood Cancer Survivor Study, a very large registry with sibling controls, found 19.6% incidence of performance limitations overall, with 7.9% unable to attend work or school for health reasons (risk ratio 5.9), and most pronounced effect after brain and bone cancers (148). Cancer survivors may be hampered by symptoms and also experience insurability concerns (especially affordability). One study of 253 long-term cancer survivors, many of whom were approaching retirement age, found 67% were actively working 5 to 7 years later, but some individuals reported that the cancer interfered with performing physical

tasks (18%), lifting heavy loads (26%), stooping, kneeling or crouching (14%), prolonged mental concentration (12%), analyzing data (11%), keeping pace with others (22%), and learning new things (14%) (149). Individuals may require extended or intermittent leave from work, and flexible work schedules. Organizations including the National Cancer Institute, American Cancer Society, Lance Armstrong Foundation, and the National Coalition for Cancer Survivorship have educational materials and programs related to employment. For those with legal questions related to employment or health insurance, the American Cancer Society's information line (1-800-ACS-2345) refers callers to the Cancer Legal Resource Center of the Western Law Center for Disability Rights. Other resources, while not specifically cancer-related, can include the Equal Employment Opportunity Commission (<http://www.eeoc.gov/>) and the Job Accommodation Network (<http://www.jan.wvu.edu/portals/individuals.htm>) (150).

## SPECIFIC TUMORS AND THEIR REHABILITATION NEEDS

### Breast Cancer

Breast cancer is the most common malignancy in women, with over 200,000 new diagnoses per year in the United States (124). The standard for treatment of breast cancer is surgical resection of the tumor with axillary lymph node assessment. The surgical procedures may be followed by any combination or chemotherapy, radiation therapy, hormonal therapy, and plastic surgical reconstruction. With approximately 2 million survivors in the United States, the rehabilitation needs of the breast cancer population have been the most studied and most documented. The most common problems include postsurgical pain, regional shoulder dysfunction, axillary pain syndromes, lymphedema (see "Lymphedema" section), and psychologic adjustment needs. In addition, for those with systemic disease, palliative care includes management of pain, bone metastases, and neurological impairments.

Postsurgical pain can occur with any breast procedure but is frequently mislabeled as postmastectomy pain syndrome. The various procedures for tumor resection include lumpectomy, partial mastectomy, quadrantectomy, simple mastectomy, modified radical mastectomy, and radical mastectomy. Axillary assessment is performed both for staging and treatment. Axillary assessment may include sentinel lymph node dissection (sampling a few lymph nodes that immediately drain the tumor) or full axillary dissection (removing all axillary nodes below the axillary vein) (125,126,151). Overall, approximately 40% of patients develop pain after the above surgical procedure that extends beyond the expected healing time (2 months). Risk factors include young age, more extensive surgery, greater immediate postoperative pain, and anxiety (126,152–154). Incidence of lymphedema is 3% to 5% for those requiring only sentinel lymph node sampling compared to 13% to 19% of patients requiring full ALND (125,151).

Postsurgical pain syndromes include phantom breast pain (155), incisional allodynia, neuroma formation, pectoralis muscle pain, and intercostobrachial neuropathy (156). Incisional allodynia is related to the dense cutaneous innervation of the breast, resulting in hypersensitivity approximating the incision. Neuroma formation typically occurs at the end of the incision and results in a focal area of pain and sometimes a small palpable mass. The pectoralis muscle may be impacted mechanically from surgery and presents with diffuse chest wall pain, worse with shoulder flexion and external rotation (157). The intercostobrachial nerve is the lateral cutaneous nerve that derives from the dorsal primary rami of the second thoracic root. It traverses across the chest wall, enters the axilla and provides sensation to the lateral chest wall and posteromedial portion of the arm. It is frequently sacrificed during axillary dissection and results in sensory impairment and occasionally allodynia.

The assessment of patients with postsurgical pain requires a history that focuses on the type of pain, functional loss, and sleep disruption from pain. The clinical exam should focus on ruling out other causes of pain, including radiculopathy, rib fracture, intercostal muscle strain, cellulitis, and systemic infection. The primary management consists of self-applied techniques including cutaneous desensitization, soft-tissue mobilization, stretching of regional muscle groups and shoulder range of motion. These techniques usually can be commenced once the surgical incision is healed. For those with persistent pain, severe loss of function, or sleep loss, additional care, including a more extended course of physical or occupational therapy, pharmaceutical management, even interventional procedures may be warranted (157). Thermal modalities should be used with caution secondary to concern of provoking lymphedema.

Breast cancer-related shoulder dysfunction is very common, affecting greater than 50% of patients and is the most common cause of long-term morbidity (157). Shoulder dysfunction typically manifests itself as rotator cuff dysfunction, frozen shoulder, or myofascial pain. The causes of the above issues are multifactorial and can be related to immobilization, muscle weakness, atrophy, mechanical alterations in the shoulder girdle musculature, radiation therapy and neurological impairment. Initially, after surgery there is a period of relative immobility to promote wound healing (see next paragraph). In addition, local irritation to the pectoralis muscles results in shortening and contraction of the muscle groups. This alteration results in aberrant length tension relationships in the shoulder girdle musculature.

The assessment of breast cancer-related shoulder pain begins with a history including postoperative complications, duration of immobilization, pain complaints, functional restrictions, weakness, and sensory symptoms. The history should also identify red flags for recurrence such as constitutional symptoms, progressive pain complaints, concurrent plexopathy or unusual presentations of lymphedema. The physical examination should identify atrophy, restriction in regional musculature; assess scapulohumeral and glenohumeral mobility, regional muscle strength and include a comprehensive neurological exam. The management of shoulder impairment

ideally begins preoperatively with a home stretching regimen to maximize shoulder mobility. After surgery, pendulum exercises and range of motion exercises below 90 degrees of shoulder abduction and flexion are advocated until postsurgical drains are removed (158). Once drains are removed, aggressive pain management and daily shoulder stretching, targeting the pectoralis complex and latissimus dorsi, are initiated. Once full range is obtained, strengthening of the scapular stabilizers, rotator cuff, and deltoid musculature should begin. For those with persistent or progressive shoulder dysfunction, advanced imaging with MRI and referral to a skilled therapist who understands cancer principles is warranted.

Intercostobrachial neuropathy (see above) and axillary web syndrome (axillary cording) are common causes of axillary pain after breast cancer treatment. In addition, seroma formation in the axilla can frequently complicate postoperative recovery. Axillary web syndrome is a band-like sensation that begins in the mid-axilla and can extend into the antecubital fossa and lateral wrist (157,159). It is due to sclerosed lymphatics and blood vessels that have lost their continuity secondary to axillary dissection (159). Patients complain of pain and shoulder restriction that is aggravated with shoulder flexion and forearm supination. This is self-limited, and usually results in a return of normal function and pain resolution with minimal intervention. The onset is usually within 2 months after axillary dissection and may be aggravated by radiation therapy. The main clinical consequence is loss of shoulder and/or elbow range of motion. Management includes massage and pressure to break up scar tissue along with shoulder mobility (160). A seroma consists of fluid that accumulates in the cavity after mastectomy and axillary dissection. Drains are placed postoperatively and typically remain until drainage is less than 30 cc over a 24-hour period, on an average 2 weeks. Persistent seroma formation leads to increased risk for infection and prolongs the restriction of activity in the upper extremity. Close surveillance and judicious use of the upper limb are standards for management.

Locoregional spread of breast cancer typically manifests itself with chest wall lesions, brachial plexopathy, or lymphedema. Change in skin contour, color, or an atypical rash in breast cancer survivors requires prompt attention and biopsy. Brachial plexopathy results from malignant seeding of the brachial plexus by tumor cells and affects 4% to 5% of breast cancer patients (161). The lower trunk is affected first resulting in shoulder, medial arm, medial forearm and fourth and fifth digit pain and sensory loss. The symptoms can progress and result in a pan-plexopathy. MRI of the brachial plexus with gadolinium is the imaging test of choice in suspected malignant spread. Radiation plexopathy may be in the differential diagnosis; presentation includes greater likelihood of paresthesias, upper trunk involvement, and myokymic discharges, and lower incidence of pain.

## Head and Neck Cancer

Head and neck cancer is the sixth most common cancer diagnosis in the United States, with approximately 40,000 cases

**TABLE 44.9** Head and Neck Cancer

Intervention <sup>a</sup>	Impairment
Glossectomy	Communication; dysphagia
Mandibulectomy	Chewing
Radical neck dissection	Shoulder depression and protraction, facial lymphedema; neck asymmetry
Radiation therapy	Contracture (neck, jaw); osteonecrosis; dental changes; decreased salivary flow; dysphagia (usually mild); trismus; CNS complications
Partial laryngectomy	Dysphagia; communication
Total laryngectomy	Communication (severe); dysphagia (mild)
Soft-palate resection	Communication; dysphagia
Nasopharyngeal tumors/treatment	Cranial nerve abnormalities
Salivary gland tumors/resection	Facial nerve palsy

<sup>a</sup>See text for treatment strategies.

per year (120,162). Squamous cell carcinoma is responsible for 95% of cases, and there is a strong association with alcohol and tobacco use (163). The primary treatment modalities for head and neck cancer include surgery, radiation therapy, and chemotherapy. Radiation and chemotherapy are used in most cases of local disease. Surgery is used for locally invasive disease and lymph node positive disease along with radiation. The morbidity of head and neck cancer is very high. Common issues include disfigurement, difficulty swallowing, impaired communication, regional shoulder girdle dysfunction, pain, soft-tissue fibrosis, and lymphedema (Table 44-9).

Swallowing dysfunction results in progressive loss of oral intake, weight loss, fatigue and ultimately decreased survival, and can affect the oral, pharyngeal and esophageal phases. Surgical removal of the tongue, mandible, or teeth results in decreased oral food processing and propagation to the pharynx. Compensatory strategies, such as forward or backward head tilts and strengthening of buccal musculature, may facilitate deglutition. Oral transit can be achieved with the use of a syringe or pusher (placement feeding) spoon. Radiation therapy can result in mucositis, xerostomia, trismus or osteoradionecrosis (120,162). Mucositis is irritation of the mucosal barrier and results in pain; this can be a result of either chemotherapy or RT. The primary management is topical agents for pain control, oral hygiene, and artificial lubrication. For severe oral pain, opioids may be utilized to maintain oral intake. Xerostomia (diminished saliva production) occurs in greater than 60% of patients receiving radiation for head and neck cancer (162). The onset of xerostomia is within days of starting RT (120). It progresses until 6 weeks after completion of RT and then gradually improves over 12 to 18 months (120). Xerostomia results in decreased lubrication of food, leading to difficulty with bolus preparation, particularly with meats and

bread. In addition, xerostomia can compromise oral hygiene and increase risk for dental caries and oral fungal infections. Radiation oncologists attempt to diminish xerostomia by parotid sparing techniques (the parotid glands produce 60% of salivary secretions), localizing RT to tumor sites and using preventative medications such as amifostine. Treatment of xerostomia consists of strict oral hygiene, including sodium fluoride gel, rinses with saline, salt and baking soda (one teaspoon of each in a quart of water) or diluted peroxide, artificial lubricants or use of a spray mister, and salivary gland stimulating agents such as pilocarpine or sugarless gum or lozenges. Diet should emphasize fluids, moist foods, and high-calorie supplements. For edentulous patients, one should wait 6 months after radiation therapy before replacing dentures secondary to gingival shrinking and remodeling. RT also may result in trismus, secondary to fibrosis of the jaw musculature. This is usually a delayed affect and can result in severe jaw mobility restriction. Prevention is through daily jaw mobilization exercises during and after RT. Treatment is through the use of therabite (Therabite Corp, Newton Square, PA), which is a utensil that provides progressive oral excursion through addition of plates. Osteoradionecrosis is a rare complication of RT that results in destruction of the jaw. This can produce severe pain and dental loss. Management is supportive. After unilateral mandibular resections, strengthening of masticatory muscles is needed to prevent drift to the nonsurgical side.

The pharyngeal phase of swallowing is impacted primarily by surgical disruption of the pharyngeal structures and by radiation fibrosis (164). Surgical disruption may be permanent and require long-term enteral feeding. Total laryngectomy does not lead to aspiration risk, as the airway and food pathway are anatomically separated by surgery; however, partial laryngectomy or sacrifice of the superior laryngeal nerve can produce aspiration risk. Many patients experience postoperative dysphagia that is transient, with as many as 85% of supraglottic laryngectomy patients attaining a functional swallow (improved from only 39% in the early postoperative period) (165). Radiation to the superior and middle constrictors results in abnormal elevation of the larynx and pharynx and resultant loss of airway protection (166). Assessment of laryngeal dysfunction is via modified barium swallow to identify aspiration. The primary management of pharyngeal dysphagia is airway protection techniques, such as breath holding during the swallow and throat clear afterward, chin tuck, and dietary modification. The esophageal phase of swallowing is primarily impacted by radiation fibrosis resulting in esophageal stricture. The primary management is mechanical dilatation of the esophagus.

Communication difficulties in head and neck cancer patients can include dysarthria, dysphonia, and aphonia. Basic strategies include use of good eye contact and appropriate gestures, as well as oral exercises for articulation and modification of pitch, loudness, and voice quality. Dysarthria is typically a result of tongue dysfunction from surgical resection or radiation fibrosis. Primary management includes early tongue mobilization and prosthetic devices. Dysphonia relates to vocal cord

**FIGURE 44-3.** Tracheoesophageal fistula for speech production in the laryngectomy patient. Diagram courtesy of InHealth Corporation.

dysfunction. This can result from RT effects or from mechanical effects of tumor, surgical resection, or neurological impairment impacting the vocal cords. Management consists of retraining primarily through a speech therapist. Aphonia is one of the most feared complications in cancer treatment and is usually a result of total laryngectomy (TL) (163). Communication after TL is through esophageal speech (propelling air into the esophagus and expelling it, making sound), electrolarynx (hand held device to the larynx that makes sound), or tracheoesophageal puncture (TEP; includes placement of a valve that allows for speech production; this approach is also known as tracheoesophageal prosthesis or fistula) (167). Esophageal speech is difficult to master with only 26% becoming facile (167). Electrolarynx results in a mechanical computerized sound that is unnatural to patients. TEP is the preferred method for communication after TL (Fig. 44-3). It results in phonation that is harsher but closer to normal than the other techniques (167). Criteria for TEP placement include no oncologic compromise, normal swallow function, reliable voice, and anatomical integrity for placement (167). Frequently, patients will require dedicated training from a speech therapist.

Salivary gland tumors often result in facial nerve impairment, either from the tumor itself or after surgery. Facial nerve palsy often recovers over a few months; nerve grafting techniques have also been employed (168).

Radical neck dissection (RND) is the most common means of surgically staging and treating locally advanced head

and neck cancer. The traditional RND removes all lymph nodes from the mandible to the clavicle, the sternocleidomastoid, accessory nerve, and external jugular vein. Recently, accessory nerve sparing procedures called functional neck dissection (FND) have become common (169). The effects of the RND include accessory nerve dysfunction, greater auricular neuropathic pain, lymphedema, and neck restriction. Accessory nerve dysfunction directly affects the function of the trapezius muscle and results in regional shoulder dysfunction. The rhomboids and levator scapula become overstretched and the pectoralis major shortened. A recent study comparing RND to FND identified less functional loss in the FND population but persistent strength and functional loss even in those receiving accessory nerve sparing procedures, suggesting stretch, compression and hypovascularity may contribute to nerve dysfunction (169). The result of trapezius loss is abnormal medial scapular stability and excessive loading of other scapular stabilizers with myofascial pain, restriction in shoulder mobility and weakness with above head activities (170). Clinically, patients present with a dropped ipsilateral shoulder, inability to shrug and forward flex the arm, restriction with above head activity and myofascial pain most notably in the levator scapulae. Management includes recumbent range of motion exercises to stabilize the scapula, followed by compensatory shoulder girdle training and education to prevent shoulder injuries. Prognosis is variable and improvement may occur over an 18- to 24-month period.

Pain is common after head and neck cancer treatments, affecting 25% to 50% of patients (162). The most common etiologies for pain include oral pain, soft-tissue fibrosis, and neuropathic pain. Oral pain can be a result of surgery, mucositis, dental caries, and osteoradionecrosis all covered in prior sections. Soft-tissue fibrosis is considered a late effect of radiation (171). Fibrosis is mediated by microvascular disruption and hyperactivation of TGF- $\beta$ , resulting in scar tissue formation (119,164). The primary effect is painful, restricted range of motion of the neck and jaw. Neck extension, rotation, and lateral bending can be severely impacted. Management is via primary prevention with daily stretching and soft-tissue mobilization techniques. Pentoxifylline and vitamin E have been used in concert to decrease fibrosis and maintain microvascular supply with variable results (119). Neuropathic pain is commonly seen from RND disruption of the greater auricular nerve. Patients can present with exquisite pain that extends from the incision site to the posterior portion of the ear. Common techniques for management include manual desensitization, topical anesthetics, and neuropathic pain medication.

Lymphedema may result from lymph node removal secondary to RND in combination with radiation changes to the lymphatics. Lymphedema of the face if uncontrolled may lead to disfigurement, swallowing impairment, respiratory compromise, and eyelid closure. Management includes manual lymphatic drainage, in combination with nocturnal compressive masks to reduce fluid accumulation in the face when recumbent (172). One study identified full remission of lymphedema

of the face with the above techniques (172). In cases of severe acute swelling, thrombosis of the superior vena cava or jugular veins should be excluded.

## Hematologic Malignancies

Hematologic malignancies often produce fatigue (173), and additional disabling effects can also occur. The most common pain syndromes include neuropathic pain from the primary malignancy, chemotherapy, or herpes zoster, bone pain related to bone marrow expansion or to osteolysis, and headache related to CNS involvement (see “Pain,” “Bony Metastatic Disease,” and “Peripheral Neuropathy” sections). Peripheral polyneuropathy occurs in 10% of patients with multiple myeloma and 15% of those with amyloidosis (174).

Lymphomas include Hodgkin’s disease and non-Hodgkin’s lymphomas. Non-Hodgkin’s lymphomas, including CNS lymphoma, are seen with increased frequency in patients with human immunodeficiency virus (HIV) and in individuals who are immunosuppressed after transplant surgery (175). Bone marrow disorders include acute and chronic leukemias and myeloproliferative disorders, such as polycythemia vera, myelofibrosis, and primary thrombocytopenia. Immunoproliferative diseases include multiple myeloma and Waldenström’s macroglobulinemia.

Lymphomas characteristically invade lymphatics but can readily invade any tissue, with non-Hodgkin’s lymphoma having a greater propensity to invade extranodal sites than Hodgkin’s disease. In addition to the bony and peripheral nerve disorders noted above, patients with history of thoracic (mantle) radiation therapy may have complications such as radiation pneumonitis, cardiac abnormalities (constrictive pericarditis, cardiomyopathy), and hypothyroidism (121). Aseptic necrosis of the femoral heads is described in 10% of long-term survivors of inverted y-field (abdominopelvic) irradiation and MOPP chemotherapy (121). Mycosis fungoides is a cutaneous T-cell lymphoma involving helper T-lymphocytes. Whirlpool treatment may be beneficial for the intractable pruritus and widespread skin scaling that can occur with this lymphoma.

Immunoproliferative diseases occur in older individuals (average age 60 at diagnosis). The skull, vertebrae, ribs, pelvis, and proximal long bones are the most common sites of involvement (121). Osteoblastic lesions are rare (incidence of <2%) and often occur with neuropathy (121). Painful pathologic fractures are common. Spinal cord or nerve root compression may occur from epidural plasmacytoma, amyloidosis, or vertebral body collapse. Cranial nerve palsies occur from tumor occluding calvarial foramina. Focal peripheral neuropathies, such as carpal tunnel syndrome, can occur from soft-tissue amyloid infiltration (121).

The leukemias can produce fatigue and bone pain. Neurologic changes may occur when white blood count is more than 100,000, due to leukostasis, and in the presence of leukemic meningitis. In children, the skeleton is often the first body system to manifest abnormality, and acute leukemia must be included in the differential diagnosis of unexplained musculoskeletal pain or bony pathology.

Rehabilitation emphasizes active exercise, including walking, to maintain endurance (stamina) during the treatment course, which is often protracted. Precautions surround the risk of bleeding in thrombocytopenic patients; pressure palsies, especially in patients receiving neurotoxic drugs or with severe immobilization; and orthostasis. Restricted bony impact is advised for extensive bony infiltration or aseptic necrosis.

Bone marrow transplant recipients have additional needs. High-dose steroids are needed to counteract GVHD, with potential complications including steroid myopathy, aseptic necrosis, and osteoporosis. The exercise program should include proximal muscle strengthening, back extension, and upper-extremity weight bearing (see “Exercise for the Cancer Patient: General Aspects”).

### Lung Cancer

Lung malignancies remain very common and are challenging for the physiatrist. Cure is possible in some cases, especially when the disease is detected early and in an operable location, but generally the prognosis remains poor. This often poses a dilemma for the physiatrist because lung cancer produces fatigue and deconditioning that occur with virtually any chronic illness (plus the fatigue of pulmonary disease), as well as many potential neurologic complications, including peripheral polyneuropathy, brain and spine metastasis, or myasthenic syndrome (see “Neurologic Complications of Cancer” section). Apical lung tumors, such as Pancoast tumor, can invade the brachial plexus or lower cervical nerve roots by direct extension, producing pain as an early symptom that is often referred to the shoulder; appropriate diagnosis may be delayed while the patient is treated for a nonexistent musculoskeletal shoulder problem. The neurologic complications often occur early in the clinical course and may even be the presenting feature. Despite a historically pessimistic outlook, in one recent study, lung cancer patients on acute rehabilitation were among the least likely to require transfer back to acute care (28). Improved exercise capacity has been reported in lung cancer patients with severely impaired pulmonary function with an 8-week intensive rehabilitation program (176).

Strategies for pain management as well as education about pulmonary hygiene and breathing techniques may be useful. Patients treated with surgical resection (either lobectomy or pneumonectomy) should be instructed in techniques to promote maximal chest expansion, including coughing, pursed-lip breathing, diaphragmatic breathing, and segmental (hand over upper or lower portion of the rib cage during inhalation) breathing exercises. Postoperatively, cough may be best tolerated with the knees flexed, and the incision splinted by firm pressure from a pillow or towel roll. Trunk posture and mobility exercise, lower-extremity exercise, and early progressive ambulation are recommended.

### Gastrointestinal Malignancies

Colorectal cancer is the fourth most prevalent carcinoma in the United States, the second leading cause of cancer death, and the only major malignancy that affects men and women almost equally. Surgery is considered the only curative

treatment, at times combined with adjuvant chemotherapy or radiation. When a stoma is present, the enterostomal nurse is a focal person in the rehabilitation process. Acceptance of the stoma is important for long-term quality of life (177). Literature on quality of life among patients with or without stoma has shown inconclusive results (177), and little data is available on long-term function in this population.

### Brain Tumors

#### Brain Tumor Types: Characteristics and Prognostic Implications

Intracranial neoplasms vary widely with respect to rate of growth, impact on function, and overall prognosis. Even a benign or relatively low-grade brain tumor may have enormous functional consequences, depending on location and the extent to which decompression is feasible. Brainstem lesions, for instance have a profound impact on motor function, specific cranial nerves, swallowing, and coordination with little possibility of resection without risk of causing even greater deficits. Communication with referring surgeons, correlation of operative reports, imaging, treatment history, and clinical examination help predict physiologic and functional recovery and allow for the selection of achievable rehabilitation goals.

#### Benign Brain Tumors

In adults, meningiomas are the most common benign brain tumor, comprising about 20% of all primary brain tumors (178). Other lesions include pituitary adenomas, acoustic neuromas, craniopharyngiomas, epidermoid tumors, third ventricle colloid cysts, and the hemangioblastomas of Von Hippel-Lindau disease. Untreated pituitary adenomas cause endocrine abnormalities, progressive bitemporal visual field loss, and headaches. Prolactinomas precipitate acromegaly and corticotrophin-secreting adenomas are the leading cause of hyperadrenocorticism, so enduringly described by Cushing in 1910 (179). Many are effectively treated with one-time surgical resection. Acoustic neuromas grow on the nerve sheath of the vestibular nerve and occur sporadically as well in patients with neurofibromatosis. Patients can develop hearing loss, vertigo, facial palsy, dysphagia, facial numbness, and even hydrocephalus. Results of microsurgery are generally good, especially with tumors measuring less than 2 cm, but local recurrence is common. Craniopharyngiomas arise from pharyngeal epithelium and cause growth failure in children and endocrine dysfunction with or without visual loss in adults as well as significant hydrocephalus. New techniques now permit endoscopic resections to avoid open craniotomy. Radiation has improved the long-term survival.

#### Malignant Brain Tumors

Ninety percent of malignant brain tumors belong to one of the three subdivisions of gliomas: (a) astrocytoma, (b) anaplastic astrocytoma, and (c) glioblastoma multiforme, each carrying a progressively poorer prognosis (178). While the incidence of primary cerebral lymphomas had increased in association with

HIV, in recent years incidence and prognosis are improving, probably due to more effective HIV regimens (175).

Low-grade astrocytomas of the cerebral hemispheres can be resected but radiotherapy is often used when tumor location precludes safe surgical excision. More aggressive surgical excisions are required for higher grade lesions unless they involve the pons, hypothalamus, or deep frontal white matter. Adjuvant radiotherapy, typically delivered to a limited field, prolongs survival. Chemotherapy appears to augment long-term survival, possibly limited to certain as yet unidentified subgroups. Current studies are assessing the synergistic efficacy of oral temozolomide, which is relatively well tolerated, given during focal radiation for glioblastoma multiforme. Younger age, higher performance rating at diagnosis, and favorable histology are associated with better outcomes (180).

### **Brain Metastasis**

See “Neurologic Complications of Cancer,” “Metastatic Brain Disease,” and “Radiation-Induced Tissue Damage” sections.

### **Rehabilitation Principles for Brain Tumor Patients**

Impaired cognition (80%), focal motor weakness (78%), and visual-perceptual impairment (53%) compromise function in brain tumor (181). Most patients have impairments in more than one domain and medical comorbidities that warrant a medically supervised rehabilitation program. Current neurologic status as well as expected clinical course determines the selection of realistic goals and rehabilitation interventions. Functional gains are possible for many patients with brain tumors but rehabilitation services for patients with steadily worsening neurological status should focus on caregiver training for palliative goals.

Rehabilitation outcomes for patients with brain tumors compare favorably to gains made by patients with other types of brain disorders such as traumatic brain injury (TBI) or stroke. Standard rehabilitation strategies for the other diagnoses (see Chapters 23 and 24) can be effectively used for brain tumor patients. Brain tumor patients participating in comprehensive inpatient rehabilitation programs have been shown to achieve meaningful gains in FIM scores with characteristically shorter lengths of stay (23,24). Concurrent radiotherapy treatment does not significantly alter these gains (26). Most studies show a higher than average rate of transfer back to an acute medical setting, but with the majority (69%) of these patients returning to meet their rehabilitation goals prior to discharge to a private home/community setting (24,26). Brain tumor patients show similar gains between those with primary brain tumor and metastatic disease (181,182); functional gains are better during the initial presentation to rehabilitation than with recurrence (183). One study examining brain tumor patients found better outcomes in meningioma patients than in those with other diagnoses and in those with left brain lesions (23).

Depression and anxiety must be treated but care should be taken when prescribing medications that may further affect cognition. Data collected from patients with gliomas have documented improvements in function with 10 mg twice daily

methylphenidate and has led to the recommendation of this agent as an adjuvant in the treatment of brain tumors (183).

Because the radiation treatments may produce fatigue, sessions should be scheduled later in the day after rehabilitation therapies have been completed (24). Continuation of oral corticosteroids is needed during radiation treatment, as edema due to radiation can precipitate or intensify neurological and cognitive symptoms. Corticosteroid regimens ranging from 2 to 24 mg/d in divided doses of oral dexamethasone or equivalent agent are typically given. Treating clinicians should be aware of potential side effects including steroid psychosis, gastrointestinal bleeding, avascular necrosis, and proximal myopathy. Anticonvulsant therapy appears to be justified in patients with a history of seizure and possibly for short-term use perioperatively, but efficacy of long-term prophylaxis for patients without history of seizure has not been established (184). Incidence of deep vein thrombosis in brain tumor patients is high, and prophylaxis, such as intermittent pneumatic compression with or without low-dose heparin, is warranted. Incidence of postoperative deep vein thrombosis may be highest in meningioma patients (72%) and lower in brain metastasis (20%) (185). Anticoagulation must be judiciously restarted in collaboration with the treating neurosurgeon following any kind of intracranial tumor resection.

### **Sarcomas of Bone and Soft Tissue**

Sarcomas are mesenchymal tumors that develop in bone and soft tissue. Although they constitute less than 0.1% of all cancer diagnoses, an incidence of over 12,000 new cases annually (186) and robust survival rates across a broad range of ages create a steady need for specialized acute as well as long-term rehabilitation services for this population. Mobility and self-care deficits are common as 45% of sarcomas involve the lower limb and 15% the upper limb (187). The remaining 40% involve the head, neck, or trunk and may result in functional impairment as well as cosmetic concerns.

Overall, soft-tissue sarcomas are three to four times more common than bone sarcomas (7). Twenty types of soft-tissue sarcoma have been identified but most types are treated similarly based on disease stage rather than tumor type. Tumor size and histologic grade are the most significant prognostic factors. Benign sarcomas including enchondromas, osteochondromas, desmoplastic fibromas, and hemangiomas produce various degrees of impairment as space occupying lesions that may require surgical intervention. Primary malignant bone tumors, as opposed to metastases or plasmacytomas (discussed elsewhere), can present in childhood, adulthood, or old age. Osteosarcoma, chondrosarcoma, Pediatric Ewing's sarcoma, and malignant fibrous histiocytoma (MFH) are the most common primary malignancies of bone. Fortunately, survival rates for both bone and soft-tissue sarcomas have increased dramatically over the past 20 years.

The key to successful oncologic and functional outcome is good local control. Early referral to centers with dedicated sarcoma programs is highly recommended as specific biopsy techniques and staging protocols increases the number of effective treatment options. Preoperative tumor cytoreduction including radiation for soft-tissue sarcomas and chemotherapy for both bone and

soft-tissue sarcomas may permit less radical surgical treatment including limb sparing surgeries in lieu of amputation (188).

### Amputation

The need to achieve wide tumor-free margins can require extensive amputations for sarcoma patients including hemipelvectomies as well as hip and shoulder disarticulations. Initial prosthetic ambulation exceeds conventional expectations for such proximal amputations because many sarcoma patients are young, with few comorbidities even after completing multi-drug chemotherapy regimens. These regimens, however, can cause transient or enduring neurologic injury to the contralateral limb in patients of all ages. As with diabetic and dysvascular lower extremity amputees, the vascular, neurological, and musculoskeletal status of the nonoperative limb has an enormous effect on balance and prosthetic ambulation. Normal aging as well as specific survivorship issues will continue to produce new rehabilitation challenges.

Many elements of upper and lower extremity prosthetic management described in Chapter 74 can be applied to patients who undergo amputations as part of their cancer treatment. Key distinctions, however, have to be taken into account (189). Patients should know in advance that recent chemotherapy or radiation often delays wound healing and should be expected to prolong the interval between surgery and prosthetic training. Expected volume fluctuations of residual limbs may be exacerbated by coexisting lymphedema after surgical resection or radiation. Irradiated skin is also more prone to “breakdown” and is less able to heal, requiring meticulous skin inspection and multiple types of socket adaptation. Preliminary socket adaptation should include variable thickness socks, flexible liners, and pressure relief.

### Limb-sparing Procedures

Advances in adjuvant treatments and surgical techniques over the past 30 years have made limb-sparing procedures a reasonable alternative for many patients (190). These patients must have a neurovascular bundle that is not compromised by tumor, have no pathologic fracture, have little extraosseous extension of tumor (for bone tumors patients), have no distant spread of tumor, and have a high probability for good cosmetic and functional outcome. Patients must be informed of the possibility of subsequent need for prosthetic revision or amputation due to infection, fracture, or prosthetic loosening (especially in athletic individuals). Close to a quarter of oncologic limb-sparing procedures will require subsequent surgical revision but less than 5% progress to amputation (191). For lower-limb procedures, energy expenditure data tend to favor the limb-sparing option over amputation (192). The cosmetic advantages of limb-sparing procedures are generally considered self-evident but comparison of quality-of-life variables between patients treated with limb-sparing procedure versus amputation has not shown a conclusive advantage to either approach (189). Quality-of-life for limb-sparing patients appears to vary with the success of the procedure; those with problematic results often report relief after the late amputation is performed.

Remobilization must be pursued slowly following limb-sparing procedures to help control edema, promote wound healing, and maintain alignment. Extensive soft-tissue resections often result in high output drainage for 1 to 2 weeks after surgery. In the absence of complications, isometric gluteal and quadriceps contraction, active assisted straight-leg raises, and ankle pumps may be started 1 to 2 weeks postoperatively. Upright activity progresses from non-weight bearing to partial and full weight bearing based on muscle strength and wound healing (193). Rotationplasty may be performed as an alternative to amputation for distal femur lesions. The ankle joint is rotated 180 degrees and replaces the absent knee joint, achieving the functional equivalent of a below-knee amputation. Because of poor cosmesis, however, this procedure is done less frequently than in the past (189).

Limb-sparing procedures may be limited to the removal of involved muscle, typically hip adductors, quadriceps, hamstrings, or gastrocnemius. Patients undergoing these procedures will need a period of bed rest until wound drainage stops. Leg elevation, compression garments, and active range of motion should be instituted as part of the rehabilitation process. Patients with extensive quadriceps excision will need a knee immobilizer postoperatively and may need to ambulate with an ankle-foot orthosis (AFO) in plantar flexion with a dorsiflexion stop so as to create and maintain an extension moment at the knee. Patients with adequate gluteal, hamstring, gastrocnemius, and soleus strength may be able to generate adequate knee extension despite the loss of their quadriceps mechanism (194). Adductor muscle group and hamstring excision rarely require assistive aides or orthotic device use. However, if the sciatic nerve is sacrificed, an AFO will be needed to provide toe clearance. When the gastrocnemius is excised, a rocker sole can be added to the sole of the shoe to promote push-off. Achilles tendon stretching should be performed regularly to maintain ankle range of motion (195).

### Prostate Cancer

Prostate cancer is the most common malignancy in men, with greater than 200,000 new cases per year (196). Disabilities from bone metastases and complications of androgen deprivation are major factors in morbidity. Men who have undergone radical prostatectomy or radiation therapy may experience incontinence and/or impotence.

Bone metastasis occurs in 85% of patients who die from prostate cancer, and is the presenting finding in 10% to 20% of prostate cancer diagnoses (197). Prostate-specific antigen (PSA) can be utilized as a screening tool with less than 2% of patients having PSA less than 10 presenting with bone disease. Treatment for advanced disease includes androgen deprivation or radiation therapy. Median life expectancy is 53 months in those with isolated bone disease and good functional scores (198). Spinal cord compression is present in 6% to 12% of patients and requires urgent management to maintain function.

Complications from androgen deprivation therapy include loss of lean body mass, fatigue, and osteoporosis. The loss of lean body mass can be attenuated by resistance training (80). Osteoporosis occurs, with a 6% to 10% loss of bone mineral

density per year (199). Greater than 33% of patients develop an osteoporotic fracture within 5 years of initiating androgen deprivation therapy (200). Preventive management includes bisphosphonates (53), exercise, and bone protection techniques (see “Cancer-Related Fatigue,” “Neurologic Complications of Cancer,” “Cancer-Related Sexual Dysfunction,” and “Bony Metastatic Disease” sections).

## CONCLUSION

Rehabilitation interventions for patients with cancer focus on preservation or restoration of function, pain relief, and education about planning and prioritizing life activities to assure quality. The rehabilitation team is in the unique position of being able to recommend practical suggestions to improve function and preserve independence throughout the course of illness whether in the settings of active disease, or the occurrence of late effects that may be experienced by cancer survivors.

## Vascular Diseases

The term *vascular disease* encompasses a variety of acute and chronic pathophysiologic syndromes caused by congenital and acquired disorders affecting the arterial, venous, and lymphatic systems. *Arterial diseases* include those acute or chronic disorders that result in partial or complete, functional or anatomic occlusion, or aneurysmal dilation of the arteries. An example of functional occlusion is abnormal vascular reactivity of the arteries supplying a given tissue such as vasospasm. *Venous disease* includes acute or chronic occlusion of the systemic venous or pulmonary arterial system, usually as a result of thromboembolism. Chronic venous disease is a spectrum of diseases and disorders of the limbs, with spider veins and varicosities on one end of the spectrum and edema, skin changes such as venous hyperpigmentation, and ulceration on the other. The cause is either primary valvular incompetence or previous deep vein thrombosis (DVT; postphlebitic/postthrombotic syndrome). Lymphatic diseases result from congenital or acquired disorders that cause obstruction, incompetence, or disruption of lymphatic vessels or the lymph-conducting elements of lymph nodes. The most frequent form of obstructive lymphatic disease is lymphedema.

In this chapter, we (a) discuss vascular diagnostic testing and focus on selected arterial, venous, and lymphatic disorders; (b) review chronic arterial occlusive diseases including acute arterial occlusions and the most frequent vasospastic vascular disorders; (c) review current evaluation and treatment of acute DVT, varicose veins, and venous insufficiency; and (d) discuss current management of chronic lymphedema.

The rehabilitation professional is often asked to evaluate the patient with a painful, swollen, or ulcerated limb. A thorough understanding of the pathophysiology, available diagnostic testing, and clinical evaluation will help the practitioner choose the appropriate vascular diagnosis and treatment regimen.

### VASCULAR DIAGNOSTIC TESTING

Vascular diagnostic testing is typically performed to confirm a clinical diagnosis and document the severity of disease. Other indications for vascular testing include monitoring disease progression, assessing outcome after an intervention, and localizing lesions to specific segments of the limb. Vascular diagnostic studies are generally classified as noninvasive (ankle-brachial index [ABI], transcutaneous oximetry) or invasive (contrast angiography, venography, lymphangiography).

### Arterial Testing

#### Ankle-Brachial Index

The ABI provides objective data about arterial perfusion of the lower limbs (Table 45-1). Pressures are obtained using blood pressure cuffs placed around the patient's lower calves or ankles. A hand-held Doppler detects systolic blood movement in the dorsalis pedis and the posterior tibial arteries. The brachial (arm) pressure is measured in the standard fashion. In normal individuals, there should be no inter-arm systolic pressure gradient, or this pressure difference should be minimal ( $<12$  mm Hg). If the arm blood pressures are not equal, a subclavian or axillary arterial stenosis is present in the arm with the lower pressure. The higher of the two blood pressures is then used for subsequent blood pressure ratio (ABI) calculations. In a healthy individual, due to peripheral amplification of the pulse pressure, the ankle pressure should be higher than the brachial arterial systolic pressure; the normal ankle-to-arm systolic blood pressure ratio is, therefore, greater than 1.0. ABI values are considered to be low-normal when they are less than 1.0 and more than 0.90, mildly diminished when they are less than 0.90 and more than or equal to 0.80, moderately diminished between 0.50 and 0.80, and severely decreased when less than 0.50. An ABI identifies individuals who are at risk for developing rest pain, ischemic ulcerations, or gangrene, and it is a marker of generalized atherosclerosis (1). The risk for death, usually from a cardiovascular event, increases dramatically as the ABI decreases. The 5-year mortality rate in patients with an ABI less than 0.85 is 10%; when the ABI is less than 0.40, the 5-year mortality rate approaches 50% (2,3).

The ABI is not accurate when the systolic blood pressure cannot be abolished using a blood pressure cuff. The incidence of noncompressible (artificially high), calcified conduit arteries is highest in diabetic, elderly, and chronic renal failure patients. Despite high recorded systolic pressure, these individuals may have severe disease. Patients with severely stenotic or occluded iliofemoral arteries may also have a normal ankle pressure if sufficient collateral circulation is present. If such patients have symptomatic evidence of arterial disease, the test should be repeated after exercise. Other diagnostic tests (segmental pressure measurement, Doppler waveform analysis, or pulse volume recording [PVR]) may also be performed to rule out significant arterial occlusive disease.

**TABLE 45.1** Diagnostic Arterial Testing

Diagnostic Tests (Arterial)	Problems to Be Assessed (Arterial)					Accurate in the Presence of Noncompressible Calcified Arteries
	Skin Perfusion	Patency	Determine Location of Stenosis/ Occlusion	Evaluate Aneurysm	Monitor Disease Progression	
Ankle-brachial index		+			+	–
Segmental pressures		+	+/-		+	–
Continuous wave Doppler		+	+		+	+
Pulse volume recording		+	+			+
Photoplethysmography	+	+/-				+

Duplex scan		+	+	+	+	+
Computed tomography		+	+	+	+	+
Magnetic resonance angiography		+	+	+	+	+
Contrast angiography		+	+	+	+	+

### Segmental Pressure Measurements

Arterial pressures can be measured using blood pressure cuffs placed at various levels (upper thigh, lower thigh, upper calf, and lower calf above the ankle) sequentially along the limb. Systolic blood pressures obtained in this manner can be indexed relative to the brachial artery pressure in a manner analogous to the ABI. Segmental pressure analysis is often used to determine the location of arterial stenoses. The presence of a significant systolic pressure gradient (>10 to 15 mm Hg) between the brachial artery pressure and the upper thigh systolic pressure usually signifies the presence of aortoiliac obstruction. A pressure gradient located between the upper and lower thigh cuff signifies obstruction in the superficial femoral artery. A gradient between the lower thigh and upper calf cuff indicates distal superficial femoral or popliteal artery obstruction. A gradient between the upper and lower calf cuffs identifies infrapopliteal disease. Gradients of 10 to 15 mm Hg between adjacent sites may represent physiologically important obstruction. Segmental pressure measurements may be artifactually elevated or unpredictable in patients with calcified or noncompressible vessels (as described with ABI). In such individuals, Doppler waveform analysis, arterial duplex studies, or transcutaneous oximetry studies may be of benefit.

### Pulse Volume Recording

PVR is used to assess the arterial pulsatility of the limb (4). An external pneumatic cuff is filled to a low pressure (typically 40 to 60 mm Hg). The pneumatic cuff is connected by a flexible hose to a pressure transducer. The blood ejected from the left ventricle during cardiac systole causes a transient distention of the limb, which in turn produces a transient rise in cuff pressure. The cyclic changes in cuff pressure with each heartbeat provide an index of arterial pulsatility. Measurements are typically made at multiple levels along the limb (as described with segmental pressures). The tracings are analyzed to determine

whether the waveform changes shape or pulse dampening occurs at a particular level (5). When an altered pulse volume waveform is present, it can be inferred that there is a hemodynamically significant lesion proximal to the site of the cuff.

### Photoplethysmography

Photoplethysmography is a noninvasive optical technique used to measure changes in the cutaneous microcirculation by detecting the reflection of infrared light. The probe contains infrared light sources and a photoelectric cell to measure reflected light. Blood is more opaque to red light than the other components of the skin and subcutaneous tissue. The amount of blood under the source beam affects the absorption of light. Photoplethysmography can be used in two ways. Using the alternating current component, the pulses recorded resemble those obtained with a strain gauge. These tracings can be used to show distal arterial disease in the hands or feet. The photoelectric cell also documents changes in extremity flow, with positional changes of the arm. This may be used to evaluate possible arterial compression at the thoracic outlet. A second method is the direct current coupling component. The DC component of the signal varies slowly and reflects variation of total blood volume of the examined tissue. With this mode, blood volume changes are recorded without major distortion. This application is used to record venous refilling after exercise (see “Venous Plethysmography”).

### Continuous Wave Doppler

Waveform analysis can provide important information that may confirm arterial patency or identify occlusive lesions (Fig. 45-1). In many circumstances, a change in blood velocity or pulse waveform such as a change from a triphasic to monophasic waveform provides reasonable, accurate information about the location and extent of specific lower extremity lesions. Doppler waveform analyses are reliable even in highly calcified vessels that are not amenable to pressure determinations.

**FIGURE 45-1.** Doppler arterial waveform. **A:** Normal (triphasic). **B:** Moderately abnormal (reduced biphasic).

### Transcutaneous Oximetry

Transcutaneous oximetry (TcPO<sub>2</sub>) determinations provide a very sensitive means to assess skin perfusion and the potential for cutaneous healing at a specific site (6). TcPO<sub>2</sub> measurements are relatively simple and reproducible. Surface oxygen-sensing electrodes calibrated to 45°C are attached to the skin and allowed to equilibrate before recording the TcPO<sub>2</sub> value. The feet are then elevated to 30 degrees for 3 minutes, and the TcPO<sub>2</sub> values are again recorded. Normal TcPO<sub>2</sub> values are greater than 50 to 60 mm Hg. TcPO<sub>2</sub> values less than 20 to 30 mm Hg suggest severe local ischemia and bode poorly for future wound healing (7). A decrease in the TcPO<sub>2</sub> value of 10 mm Hg with an elevation is significant (6) and suggests tenuous perfusion.

### Duplex Scanning

Duplex scanning using B-mode imaging combined with directional Doppler can visualize and assess arterial aneurysms and detect flow velocity changes at sites of localized stenosis or occlusion. Duplex studies can assess plaque morphology, surgical graft patency, and establish the presence of arteriovenous fistulae. This technique requires a technically proficient examiner, may require extensive time for a complete examination, and is significantly more expensive than most physiologic noninvasive testing methods. Duplex scanning is particularly helpful in assessing proximal iliofemoral stenosis that may be amenable to angioplasty, providing follow-up data to assess continued patency of both venous and prosthetic arterial grafts, and evaluating the patency of prior angioplasty sites or intravascular stents.

### Imaging Techniques

Technological advances are enabling computed tomography (CT) and magnetic resonance angiography (MRA) to replace conventional angiography as a means of identifying arterial stenoses and occlusions.

### CT Angiography

During the past decade, CT angiography (CTA) has become a standard noninvasive imaging modality for vascular anatomy and pathology. With continued improvement in spatial resolution, CTA is now the mainstay for preoperative imaging of abdominal aortic aneurysms. It provides accurate information not only of the size of an aneurysm but also the exact location and critical measurements needed for repair.

CT with three-dimensional reconstruction provides a global view of the chest, abdomen, and associated large vessels (Fig. 45-2). The accuracy is less operator-dependent when

**FIGURE 45-2.** CTA of the infrarenal abdominal aortic artery showing an occlusion just below the level of the left renal artery. The aortic occlusion is chronic with well-developed collaterals.

compared to ultrasound and is especially useful in patients with a large body habitus. CTA requires radiation exposure for image acquisition.

### Magnetic Resonance Angiography

MRA can be used to determine the morphology of blood vessels, assess blood flow velocity, evaluate the lumen for the presence of thrombosis, and evaluate for the presence of hemorrhage, infection, or the status of the end organ. MRA has been found to have a sensitivity of 99.6%, a specificity of 100%, a positive predictive value of 100%, and a negative predictive value of 98.5% for detecting patent segments, occluded segments, and hemodynamically significant stenosis in the aorta, iliac, and femoral vessels (8). Unlike ultrasound, MRA is not compromised by overlying bone, bowel gas, or calcification. When MRA is compared with conventional contrast angiography in preoperative studies of the aorta, iliac artery, and femoral artery, the two imaging modalities are concordant in almost all cases (8). MRA is relatively expensive and its use limited in situations in which metallic instrumentation may be required. MRA is the optimum imaging alternative in pregnant patients and patients with severe iodinated contrast allergy.

Magnetic resonance studies using gadolinium have a long safety record with little nephrotoxicity at the doses used. Recent reports that gadolinium may play a role in inducing nephrogenic systemic fibrosis (NSF) are a concern. Although rare, NSF can be catastrophic. Caution is recommended with reduced glomerular filtration rate (GFR) (definitely, a GFR <30, possibly <60) (9,10).

### Contrast Arteriography

Contrast angiography has been the traditional “gold standard” for lower extremity arterial evaluation. Angiography remains the definitive approach for preoperative evaluation in patients requiring revascularization. Pre-procedure arteriography is an essential part of endovascular procedures. Digital subtraction angiography allows enhanced visualization of the structures of interest.

Conventional angiography is associated with an overall minor and major complication rate of about 8%. Most of the complications result from the side effects of the iodinated contrast material and access site complications. Patients with

preexisting renal insufficiency, diabetes, or dehydration are at greatest risk for contrast-induced renal failure. To minimize the risk of nephrotoxicity, bicarbonate hydration and oral acetylcysteine can be used starting the day prior to the procedure. The risk for contrast reaction varies from 0.04% to 0.22% (11,12). The arterial puncture necessary for the study may be associated with bleeding, hematoma, pseudoaneurysm, and pain at the site. There is also modest risk for contrast allergy, which can be associated with anaphylaxis, or death, and contrast-induced worsening of renal function (11).

### Venous Testing

#### Continuous Wave Doppler

Continuous wave Doppler (described previously) is also used clinically to test the integrity of the venous system (Table 45-2). This method can identify the presence of venous obstruction or incompetence, quantify severity of the venous disease, and roughly localize these abnormalities to a particular segment of the limb. The venous flow signal is obtained at several sites in the limb. Normal venous flow is spontaneous and phasic with respiration. With continuous wave Doppler, the patency, spontaneous flow, phasicity, augmentation, competency, and pulsatility of the venous flow are determined and graded. Obstruction of a vein is characterized by the absence of normal spontaneous venous flow or by the loss of phasic variation with respiration. If the Doppler probe is placed directly over an obstruction, there is absence of spontaneous flow. If the probe is placed below the site of obstruction, there is a loss of phasic change in the venous flow with respiration (a monophasic low-frequency signal). Several maneuvers (deep breathing, Valsalva, and distal compression of the calf or forearm) can produce augmentation of venous flow. Because continuous wave Doppler provides subjective information, if positive for obstruction, findings should be followed by an objective test.

Venous Doppler ultrasound examination is portable and inexpensive. Validation studies of continuous wave Doppler ultrasound for lower extremity deep vein thromboses (DVT) report a sensitivity of 31% to 96% and a specificity of 51% to 94% (13,14). Limitations with venous Doppler ultrasound include (a) the need for examiner expertise; (b) only thrombi in the major deep veins in direct continuity with the heart can be detected (an isolated thrombi in

**TABLE 45.2 Diagnostic Venous Tests**

MR or CT imaging	+		+

<sup>a</sup>Acute DVT only.

## Venous Examination

**FIGURE 45-3.** Tracings (normal and abnormal) for outflow plethysmography, passive draining and refilling, and exercise plethysmography are shown for a normal (right leg) and abnormal (left leg) study. In the normal leg, the outflow plethysmography shows rapid return to baseline following cuff release (i.e., there is no significant obstruction), the passive draining and refilling shows a slow recovery to baseline volume following passive draining (i.e., there is no venous incompetence), and the exercise venous plethysmography shows a pronounced drop in ankle volume during and immediately after exercise, with slow return to baseline (i.e., there is a good calf muscle pump function). In the abnormal limb, all three of these tests are abnormal.

tributaries such as the internal iliac, deep femoral, peroneal, gastrocnemius, and soleus veins will likely be missed); (c) to be detected, the thrombus must produce a flow disturbance (nonocclusive thrombi may be missed because venous flow is present in anatomically adjacent collaterals); and (d) external compression of the vein cannot be distinguished from internal thrombosis. Because of these limitations, continuous wave Doppler ultrasound has largely been replaced by venous duplex scanning for the diagnosis of DVT (combines Doppler principles with real-time B-mode and color-flow ultrasound imaging).

### Venous Plethysmography

Plethysmography is a noninvasive method of detecting blood volume changes in an extremity (Fig. 45-3). Plethysmographic techniques have been developed to measure the changes in limb volume that occur when venous return is enhanced (venous insufficiency) or impeded (venous obstruction). With normal venous outflow, positional change (leg elevation) or release of an externally inflated cuff results in rapid emptying

of the leg veins. If the valves are competent, refilling occurs in an antegrade fashion through the arteries and capillaries. In normal individuals, this takes a minute or more.

With venous incompetence, the leg volume returns to baseline more rapidly than normal. If the incompetence is primarily superficial, tourniquets placed around the leg or using a finger to compress an incompetent superficial vein will normalize the refilling time. In venous obstruction, the peripheral venous pressure and baseline venous volume are elevated (increased venous outflow resistance). In this case, leg elevation or a rapid release of the cuff results in slower emptying of the leg veins.

Segmental plethysmography uses a sleeve to demonstrate changes in limb volume. Sequential timed inflation and deflation of a proximal cuff produces changes in limb volume, which are measured to determine the venous capacitance and maximal venous outflow. The presence of a proximal lower extremity DVT causes (a) minimal change in the limb volume with cuff inflation and (b) a decreased change in limb volume when the cuff is released.

### Duplex Ultrasound

Duplex ultrasound (a) directly visualizes and locates intraluminal obstruction; (b) assesses the characteristics of venous flow distal to the inguinal ligament; (c) identifies the presence of collateral veins around an obstructed venous segment; (d) permits direct detection of valvular reflux; (e) allows visualization of specific venous valves and valve leaflet motion; (f) quantitates the degree of incompetence; (g) locates and assesses veins before harvest for bypass procedures; (h) evaluates venous perforator incompetence; and (i) evaluates conditions that may mimic venous disease. Duplex scanning has become the method of choice for testing individual veins of the superficial, deep, and perforating systems.

### D-Dimer

D-Dimer is a global indicator of coagulation activation and fibrinolysis. D-Dimer level is measured in plasma by use of well-standardized assays that are widely used for the diagnosis of acute venous thromboembolus (VTE). In patients with a first VTE, measuring D-Dimer level allows a global assessment of their thrombotic tendency and a stratification into high- and low-risk patients with regard to risk of recurrence. Patients with a first spontaneous VTE and a D-Dimer level of less than 250 ng/mL after withdrawal of oral anticoagulation have a low risk of VTE recurrence (15). In patients with thrombosis with a very low risk of recurrence, extensive screening for thrombophilic risk factors may be unnecessary.

### Contrast Venography

Lower extremity contrast venography remains a powerful, but decreasingly used tool, in the evaluation of both acute and chronic DVT. At this time, ascending leg venography is rarely used to confirm acute DVT. With advances in duplex ultrasonography, venography has been largely replaced by duplex scanning to evaluate patients with suspected deep venous obstruction or incompetence. It is indicated when a high clinical suspicion of thrombosis is present and noninvasive testing is negative or equivocal (16). In chronic venous disease, ascending venography demonstrates the location and extent of postthrombotic disease, as manifested by occlusion, venous recanalization, collateral channels, and superficial varicosities. Ascending venography may also help with planning of endovascular and open surgical procedures such as iliac and Inferior vena cava (IVC) recanalizations and venous bypass grafts. Ascending contrast venography is performed primarily in patients with significant chronic deep venous occlusive disease who are candidates for endovascular treatment with stents, surgical venous bypass, venous valve repair, or valve transplantation. Descending venography is used in concert with ascending venography to distinguish primary valvular incompetence from thrombotic disease. Descending venography identifies the level of deep vein reflux and evaluates the morphology of the venous valves. With decreasing experience using this technique, the “gold standard” is uninterpretable in 5% to 15% of patients (17). Unfortunately, the numbers of poor-quality

examinations will likely increase in the future as the need for venography continues to decline.

### CT Venous Imaging

The two advantages of CT in venous imaging are the speed and resolution of image acquisition. The disadvantages include radiation exposure and the necessity for administration of iodinated contrast material. Patients with a significant allergic reaction to iodinated contrast material or decreased renal function should be evaluated with alternate imaging techniques.

### Magnetic Resonance Imaging

The effectiveness of MRI for detection of DVT has been compared with that of contrast venography in a number of trials. Sensitivity and specificity values as high as 100% have been reported (18). MRI can also be used to distinguish acute from chronic DVT. Because MRI is more expensive than a duplex scan, it is rarely used to diagnose DVT.

### Lymphatic Testing

#### Lymphoscintigraphy

Lymphoscintigraphy, performed by injecting a radioactive colloid and observing uptake into the lymphatic system, has become the standard evaluation tool to establish lymphatic flow patterns (19,20). This test can be performed in both upper and lower extremities by injecting the colloid between the digits of the hands or toes, respectively. Lymphoscintigraphy assesses the most basic function of the lymphatic system, namely the clearance of interstitial macromolecules that are too large to reenter the blood capillaries directly. When lymphedema is present, the images often show a highly characteristic dermal backflow pattern or re-routing of tracer away from the main lymphatic trunks and into fine collateral lymphatic vessels of the skin. Images may also suggest distal or proximal lymphatic obliteration, hyperplasia, or aplasia/hypoplasia of lymphatic vessels. Because lymphatic disease occurs so rarely, the skills for administration and accurate interpretation of this test are often available only in larger medical centers where higher volumes of testing occur.

#### Lymphangiography

Lymphangiography should not be considered unless specific surgical intervention is being contemplated. It is invasive and may damage the (remaining) lymphatic vessels (21).

### Lymphatic Imaging

The studies described earlier help distinguish venous disease from lymphatic disease. CT scan of the abdomen is helpful to discover the underlying obstructive pathology and should be part of an evaluation of new edema in the lower extremity (22,23). MR imaging is useful in studying the swollen limb without obvious etiology because fluid, fat, soft tissue, and tumor can all be identified (24). Ultrasound imaging may provide accurate measurement of clinical lymphedema in the future.

**FIGURE 45-4.** Chronic arterial occlusive disease with ischemia, cutaneous ulcerations, and gangrene.

## ARTERIAL DISEASES

### Arteriosclerosis Obliterans

The presentation of arterial occlusive disease varies with the time course of progression and the presence and extent of collateral vessels, comorbidities, and activity of the patient. Patients with peripheral arterial occlusive disease commonly present with symptoms of intermittent claudication or critical leg ischemia. If the patient is active, intermittent claudication is the typical presenting complaint. If the patient is inactive, rest pain, ulceration, dependent rubor, or gangrene may be the presenting finding (Fig. 45-4). In general, symptoms occur distal to the level of stenosis.

Intermittent claudication indicates an inadequate supply of arterial blood to contracting muscles. It occurs primarily in chronic arterial occlusive disease or severe arteriospastic disease. Intermittent claudication is brought on by continuous exercise and is relieved promptly by rest without change of position of the affected limb. Patients describe claudication as leg numbness, weakness, buckling, aching, cramping, or pain. It may change in character as the causative lesions progress. Claudication occurs at a predictable distance or time. When the workload is increased (rapid pace, walking up hills, or walking over rough terrain), the time to claudication decreases. Claudication may worsen over a period of inactivity (e.g., when the patient is hospitalized) but usually returns to baseline with reconditioning. When claudication abruptly increases, one must consider thrombosis *in situ* or an embolic event. Claudication at the arch of the foot suggests occlusion at or above the ankle; claudication at the calf suggests occlusion at or above this region. Claudication is less frequent above the knee (probably because of the rich collateral circulation in the thigh); however, occlusion of the iliac arteries or aorta may cause thigh, lumbar region, and buttock claudication (25).

Although many other disorders can cause the symptoms of lower extremity arterial insufficiency (thromboangiitis obliterans, arterial thromboemboli), these conditions account for

only a small percentage of lower extremity arterial disease. Nevertheless, recognition of the broad differential diagnosis of lower extremity arterial disease is important to optimize management. Progression of lower extremity arterial occlusive disease may be slow. In patients presenting with intermittent claudication, symptomatic worsening occurs in 15% to 30% over 5 to 10 years following the initial diagnosis. Tissue necrosis or progression to rest pain requiring vascular surgery occurs in 2.7% to 5% of limbs with claudication annually. Amputation is required in 1% per year (26).

### Treatment

#### Medical

The management of patients with intermittent claudication has traditionally focused on relief of symptoms. The goals of medical care should be to reduce cardiovascular risk and alleviate symptoms of intermittent claudication. Medical therapies can effectively modify both the natural history of atherosclerotic lower extremity arterial occlusive disease and significantly reduce the morbidity of this disorder.

Screening for elevated homocysteine should be considered in young patients with peripheral arterial disease (PAD). An elevated plasma homocysteine level is emerging as a prevalent and strong predictor for atherosclerotic vascular disease in the peripheral, coronary, and cerebral vessels and is recognized as an independent predictor of PAD (27). An increased plasma total homocysteine level confers an independent risk for vascular disease similar to that of smoking or hyperlipidemia. It further increases the risk associated with smoking and hypertension (28). Elevated homocysteine levels can be lowered by folic acid and other vitamin supplementation; however, no studies to date have examined how this treatment affects atherosclerosis or intermittent claudication symptoms (29).

Among apparently healthy men, elevated baseline levels of C-reactive protein (CRP), a marker for systemic inflammation, may predict future risk for developing symptomatic peripheral arterial occlusive disease. CRP may serve as a molecular marker for underlying systemic atherosclerosis (30).

**Risk factor management.** All patients presenting for treatment of peripheral arterial occlusive disease should have their risk factors rigorously assessed (31). Patients with known PAD should be treated aggressively with a combination of a HMG CoA reductase inhibitor (statin), an angiotensin-converting enzyme (ACE) inhibitor, an antiplatelet agent, and a  $\beta$ -blocker (if there is a history of coronary disease). They should also control their blood pressure and blood sugar level. Smokers should be encouraged to stop smoking (32). On average, an age-matched control group has an all-cause mortality rate of 1.6% per year. This rate increases to 4.8% per year for patients with PAD. Cardiovascular mortality rates are similarly affected, with an overall event rate of 0.5% per year in controls and 2.5% per year in patients with PAD. The presence of PAD is an independent risk factor for mortality even when other known risk factors are controlled (32–35). Treatment needs to focus on both the effects of atherosclerosis in the peripheral circulation

and the systemic nature of the disease. Appropriate therapy should be instituted to decrease the risk for both peripheral progression and cardiovascular mortality.

The increased cardiac event rate in patients with PAD underscores the importance of intensive medical management to reduce the risks for cardiovascular morbidity and mortality.

**Diabetic management.** The effect of diabetic management on large vessel arterial occlusive disease has not yet been evaluated in a controlled prospective clinical trial. Optimal diabetic management is presumed to improve the rate of lower extremity disease progression and to decrease the incidence of wound infection, gangrene, and amputation (36).

**Nicotine cessation.** Cigarette smoking is an exceptionally positive risk factor for lower extremity PAD. It is 2 to 3 times more likely to cause lower extremity PAD than coronary artery disease (37). Cigarette smoking nearly doubles the risk for progression of peripheral arterial occlusive disease, independent of other associated risks factors (31). Patients should be informed that continued tobacco use is likely to accelerate disease progression and cause progressive symptomatic worsening. Eighteen percent of patients with claudication who continue to smoke cigarettes develop rest pain over the subsequent 5 years of observation (38). In contrast, in those patients who stop smoking, the development of rest pain is exceedingly rare. The 5-year mortality rate for patients with claudication who continue to smoke may be as high as 40% to 50%.

**Lipid management.** Effective lipid management should be considered a mandatory component of the medical therapy of patients with objective evidence of atherosclerotic peripheral arterial occlusive disease. Patients should be treated with diet and pharmacologic therapy to achieve low-density lipoprotein (LDL) cholesterol levels of less than 100 mg/dL (39). Statins have favorable effects on multiple interrelated aspects of vascular biology important in atherosclerosis. In particular, they have beneficial effects on inflammation, plaque stabilization, endothelial dysfunction, and thrombosis. Statins have also been shown to be beneficial in acute vascular events.

**Hypertension management.** The goal of treated hypertension in patients with PAD should be similar to that in patients who have other cardiovascular disease. Antihypertensive therapies should be administered to hypertensive patients with lower extremity PAD to achieve a goal of less than 140 mm Hg systolic/90 mm Hg diastolic (nondiabetics) or less than 130 mm Hg systolic/80 mm Hg diastolic (diabetics and individuals with chronic renal disease) to reduce the risk of MI, stroke, congestive heart failure, and cardiovascular death (36,37).

**ACE inhibitors.** ACE inhibitors have been shown to reduce cardiovascular morbidity and mortality rates in patients with PAD by 25% regardless of the presence or absence of hypertension (28).

**Antiplatelet therapy.** Antiplatelet therapy may decrease the rate of atherosclerotic disease progression, decrease the incidence of thrombotic events in the limbs, and decrease the rate of adverse coronary and cerebral vascular ischemic events.

Aspirin in doses of 75 to 325 mg is recommended as safe and effective antiplatelet therapy to reduce the risk of MI, stroke, or vascular death in individuals with atherosclerotic lower extremity PAD (36). Patients with documented arterial occlusive disease may benefit from antiplatelet therapy unless otherwise contraindicated. The relative benefits of newer antiplatelet drugs on limb ischemic event rates and patient survival are presently under investigation. Ticlopidine and clopidogrel are thienopyridines that selectively inhibit the adenosine diphosphate (ADP) platelet receptor with no direct effects on arachidonic acid metabolism (40,41). Ticlopidine has been evaluated in patients with intermittent claudication. In a multicenter, randomized, controlled trial of patients undergoing treatment with ticlopidine versus placebo (STIMS), the need for subsequent vascular surgery was reduced by about 50% over a 7-year time period (42). The use of ticlopidine has dropped markedly owing to blood aplastic side effects. In platelet-aggregation studies, clopidogrel, 75 mg once daily, produced inhibition of ADP-induced platelet aggregation equivalent to that of ticlopidine, 250 mg twice daily. Long-term administration of clopidogrel in patients with atherosclerotic vascular disease has been reported to be more effective than aspirin in reducing the combined risk for ischemic stroke, myocardial infarction, or vascular death (43).

**Prostaglandins.** Prostacyclin and its analogues prostaglandin E<sub>1</sub>, prostaglandin I<sub>2</sub>, and iloprost (a prostaglandin I<sub>2</sub> analogue) have been shown to improve perfusion through (a) inhibition of platelet aggregation, (b) decreased leukocyte migration and activation, (c) vasodilation (possibly through an effect on resting sympathetic tone), and (d) profibrinolytic effects. Iloprost is typically infused for 6 hours per day for 28 days (2 ng/kg/min). Iloprost was shown to decrease the probability of dying or requiring major amputation during treatment and the subsequent 3 to 6 months (44). Oral vasodilator prostaglandins such as beraprost and iloprost are not effective medications to improve walking distances in patients with intermittent claudication (36).

**Vasodilator drugs.** In general, vasodilator drugs do not improve symptoms in patients with arterial claudication. Direct-acting vasodilators have minimal effect at the focal atherosclerotic site. Vasodilator drugs do not vasodilate lower extremity collateral vessels. In addition, this class of medications may elicit a fall in blood pressure and limb perfusion pressure if a preferential vasodilatory effect occurs in other nondiseased circulation (45).

**$\beta$ -Blockers.** Although  $\beta$ -blockers were previously believed to have detrimental clinical effects in patients with claudication, clinical trials have demonstrated a symptom-neutral effect for these agents in most patients (46). Because  $\beta$ -blocker therapy may be efficacious for the treatment of associated coronary artery disease or myocardial infarction, these drugs do not need to be empirically withdrawn from the patient with claudication.

**Agents for intermittent claudication.** Cilostazol inhibits the action of phosphodiesterase and increases the amount of intracellular cyclic adenosine monophosphate. This results

in significant platelet and vasodilatory activity as well as antiproliferative properties. Since antiplatelet and vasodilatory drugs have been shown to have no positive effect on claudication-limiting walking distance, the mechanism by which Cilostazol achieves improvement in PAD patients remains speculative (47). Cilostazol (100 mg orally two times per day) is indicated as an effective therapy to improve symptoms and increase walking distances in patients with lower extremity PAD and intermittent claudication (in the absence of heart failure) (36). This medication is contraindicated in patients with congestive heart failure.

Pentoxifylline has received variable reports of success in patients with arterial occlusive disease (48). Minimal efficacy and caffeine-like side effects limit use of this medication.

**Antioxidants.** Antioxidant agents may render LDL cholesterol resistant to oxidation and make that lipid fraction less atherogenic. In addition, antioxidants may improve endothelium-dependent vasodilation by reducing oxidative degradation of nitric oxide (49). A number of descriptive and case-controlled studies have shown an association between antioxidant agents (vitamins E, C, and  $\beta$ -carotene) and reduction in cardiovascular events (50). Further studies are required to evaluate if oxidative stress and antioxidant status are implicated in the clinical progression of disease and to define the formulation and dosing of antioxidant vitamins. Although the basic science is promising, large randomized controlled trials have yet to show a compelling agent that will bring these clinical effects to fruition.

In summary, although there are few widely accepted pharmacologic interventions for PAD, current recommendations are that all PAD patients should receive antiplatelet therapy, stop smoking, exercise, and be screened and treated for hyperlipidemia, hypertension, diabetes, and hypercoagulability in accordance with national guidelines and community standards (51).

## Rehabilitation

**General self-care measures.** Patients with PAD should be instructed to wear protective footwear at all times (never walk barefoot or in socks) and monitor their extremities carefully for redness or skin breakdown. Extremes of temperature should be avoided. The feet should be washed carefully with mild soap and warm water. Drying is best performed by blotting or patting with a soft clean towel (rubbing should be avoided because it may injure the skin). The skin between the toes should be carefully dried to avoid maceration. Emollients without preservative or perfume should be used (avoid between the toes) to prevent cracking of the skin. Proper footwear, which avoids producing areas of point pressure, should be used. Whenever new shoes are purchased, the patient should gradually (over a period of a week) wear-in shoes to make sure there are no areas of point pressure with the new footwear. Warm outer footwear should be used in the winter to protect against cold injury.

Decreased activity secondary to symptomatic lower extremity arterial occlusive disease can result in deconditioning, which

further contributes to disease impairment. Deconditioning may also be “iatrogenic” as a result of a prolonged period of limited mobility to avoid trauma to ischemic wounds.

**Exercise.** Regular exercise training produces a reduction in the inflammatory markers associated with endothelial damage (37). Evidence suggests that patients following an exercise regimen improve both their claudication distance and cardiovascular risk profile (51). Exercise training may elicit improvements in maximal walking time of 25% to 200% (52). On average, patients can expect to double their intermittent and absolute claudication distances. Exercise training has been postulated to improve performance in patients with claudication by directly augmenting limb flow, improving blood viscosity, biomechanically improving the efficiency of gait, and altering the ischemic pain threshold or tolerance. To optimize the benefits of an exercise program, patients should receive a structured claudication exercise rehabilitation program for at least three sessions weekly over a period of 12 weeks (52–56). Continued improvement can be seen over 24 weeks of training. Strength training, whether sequential or concomitant, does not augment the response to a walking exercise program (57). The optimal exercise program for improving claudication pain distances in patients with PAD is intermittent walking to near maximal pain during a program of at least 6 months. Such a program should be a part of the standard medical care for patient with intermittent claudication (58). Patients should be instructed to walk until claudication occurs, rest until it subsides, and continue, repeating the cycle for 1 hour each day. Improved walking performance has also been demonstrated through upper limb aerobic exercise training in patients with PAD (59).

## Gene Therapy

Molecular therapies to induce angiogenesis are appealing in the claudicant population because: ischemia is subacute, time is available for angiogenesis to occur, and collateral development is associated with increased walking distance. Molecular therapies that result in increased levels of vascular endothelial growth factor, fibroblast growth factor, and hepatocyte growth factor have been used in claudication populations. The RAVE trial (regional angiogenesis with vascular endothelial growth factor in PAD) concluded that a single IM administration of endoviral vascular endothelial growth factor was not associated with improved treadmill exercise performance or quality of life over placebo (60).

## Revascularization

Previously, surgical revascularization was considered for patients with rest pain, pending tissue loss, or significant limitations of lifestyle who failed medical treatment. Endovascular intervention coupled with aggressive proactive medical management is replacing these conventional paradigms (51).

**Endovascular.** Endovascular therapy is a broad term that encompasses several treatment modalities: percutaneous transluminal angioplasty (PTA), stenting, stent-grafting (e.g., Viabahn and aortic stent grafts), atherectomy, cryoplasty, cutting-balloon angioplasty, and laser-directed atherectomy.

PTA is indicated for focal stenosis or short segmental occlusions in which the adjacent vessels are relatively free of disease. A localized stenosis of the common iliac artery (<5 cm in length) is the most favorable situation for angioplasty (61). Iliac PTA for focal iliac disease is also a valuable adjunct when combined with distal surgical revascularization in appropriate patients with multilevel disease (62). Angioplasty is a controlled injury to the vessel wall (51). Smooth muscle cell proliferation within the media (normal <1%), increases to more than 20% within 48 hours after angioplasty. After balloon angioplasty, there is thrombosis formation, intimal hyperplasia development, elastic recoil, and remodeling. In contrast after stent placement, elastic recoil and remodeling are eliminated, and thrombosis followed by intimal hyperplasia is the main contributor to in-stent restenosis (51).

Endovascular stents were introduced to help resolve the problems of residual stenosis, elastic recoil, flow-limiting arterial dissection, and to improve patency rates after balloon angioplasty. The response of a vessel to a stent is dependent on the stent design, length, composition, delivery system, and deployment technique (51). Initial results of stents placed for treatment of occlusive atherosclerotic disease in femoral and popliteal arteries showed promising results. Subsequent studies demonstrated that exaggerated neointimal hyperplasia in the stent-treated segment frequently leads to in-stent restenosis. The biology of in-stent restenosis is different than that seen after balloon angioplasty. In a retrospective study, nitinol stents significantly improved primary patency rates in femoropopliteal arteries compared with stainless steel stents (63). In the intermediate term, a randomized controlled study has shown superior results with nitinol stents compared to PTA with the option of secondary stenting (64). The policy of routine primary stenting versus angioplasty for femoropopliteal lesions remains controversial. Primary stenting adds to the cost and treatment failures are more difficult to manage than those with angioplasty alone (65).

The potential role of radiation in the prevention of restenosis has been evaluated. Ionizing radiation inhibits cellular proliferation and has been used in the treatment of neoplastic and non-neoplastic diseases. Endovascular brachytherapy has shown a delay but not an inhibition of restenosis when compared to PTA alone (66).

Cryoplasty is a novel therapy that combines conventional balloon angioplasty with application of cryotherapy. The hope is that cryotherapy will allow more accurate angioplasty; reducing dissections and vessel response to injury (51). This modality may have a role in the treatment of lesions across the knee joint or in patients with restenosis after standard angioplasty.

There is decreasing long-term effectiveness of PTA in more distal vessels because of the reduction in both artery size and flow rate. It is reasonable to consider distal angioplasty for limb salvage in patients at high risk for limb loss who are not surgical candidates. Although the rate of long-term clinical success appears to be less than that for conventional surgical reconstruction, the benefits in terms of decreased morbidity and probable cost savings may well justify the use of PTA in these

circumstances. At present, PTA is generally not recommended for patients with diffuse iliac artery disease unless they are extraordinarily poor surgical candidates.

*Subintimal recanalization.* Subintimal recanalization of infrainguinal occlusions is a minimally invasive percutaneous endovascular technique that allows revascularization of occluded infrainguinal arteries by creating a new lumen between the intima and the adventitia of the arterial wall. Unlike conventional PTA, subintimal angioplasty displaces the atheromatous and calcified intima and media to one side of the vessel lumen thereby producing a relatively smooth neolumen. The catheter and wire are redirected to the true arterial lumen distal to the area of occlusion. Subintimal recanalization can be used in patients with critical limb ischemia (67). These patients frequently have multiple comorbidities and consequently long-term survival is poor, irrespective of the technique used to revascularize the ischemic limb. The success rate of subintimal recanalization has been reported to be 78% to 90% depending on the length of the occluded arterial segment treated. Patency rates are approximately 50% at 1-year follow-up, with higher (70% to 80%) limb salvage rate. The most common complications include peripheral embolization, inadvertent ruptures, and bleeding. Other alternative endovascular modalities in patients with long-segment disease include percutaneous atherectomy devices (Silverhawk) and laser-directed atherectomy.

*Endovascular aortic aneurysm repair (EVAR).* Interventions for repair of abdominal aortic aneurysms have undergone significant evolution since the introduction of EVAR more than a decade ago. The aim of open surgical or endovascular treatment of abdominal aortic aneurysms is to prevent rupture. The size criteria and indications for repair are the same for both open or endovascular repair. Initial results with endograft placement for abdominal aortic aneurysm were promising yet issues regarding durability prohibited widespread use of the original devices. Anatomic considerations that traditionally preclude repair are now being overcome with these advancing technologies. The complications of endovascular repair include groin wound complications, stent-graft migration, and leak. As the technology has evolved, less device-related complications are being seen. The need for continuous postoperative surveillance, the high cost of the device, complications, re-interventions, late ruptures, and lack of evidence of improved late mortality or a better quality of life continue to raise questions of the durability and specific indications of EVAR. EVAR should be offered for high risk or elderly patients with suitable anatomy for endograft repair and selected patients with symptomatic, ruptured abdominal aortic aneurysm (68). With the introduction of fenestrated and branched graft technology, an increasing number of patients will undergo endovascular repair in the near future.

*Surgical.* Open repair remains the gold standard for the treatment of abdominal aortic aneurysm. The mortality rate from aortic aneurysm repair has traditionally been very low (<5%). Based on prospective randomized multicenter studies, surgical treatment is recommended over observation for males

with an abdominal aortic aneurysm of 5.5 cm in diameter or greater and for females who have an aortic aneurysm of 5.0 cm or greater in diameter (69). If the aneurysm is smaller, observation with serial ultrasounds or CT scans every 6 months is warranted. The “normal” growth rate is approximately 3 to 4 mm per year (36). Open surgery (transabdominal, retroperitoneal, or mini-laparotomy) should be offered as the first option to low risk patients less than 70 years of age.

Ischemic rest pain and tissue necrosis, including ischemic ulceration or gangrene, are well accepted as indicators of advanced ischemia and threatened limb loss. Without treatment, most limbs with these symptoms experience disease progression and require major amputation. These symptoms represent an unequivocal indication for arterial revascularization, if anatomically feasible. Large vessel bypass surgery with synthetic graft material is well established and durable. Aortobifemoral grafting continues to be regarded as the gold standard for the treatment of aortoiliac occlusive disease (70). If early and long-term patency is to be achieved, it is important that the site for vascular reconstruction has a relatively unobstructed inflow and a patent distal runoff.

The purpose of profundoplasty is to relieve a significant stenosis or an occlusion of the proximal portion of the deep femoral artery in order to restore its function. The procedure is employed as an adjunct to an inflow procedure or when patients present with an occluded limb of an aortobifemoral bypass. The profunda femoris artery is often the only major outflow vessel in the groin. In this case, a profundoplasty ensures continued patency of the aortofemoral limb. In addition, profundoplasty can be performed to optimize healing after transtibial amputation.

Judicious selection of the appropriate method of infrainguinal reconstruction for a given patient requires an appreciation of the results obtained with all available approaches. Although PTA may be appropriate for some patients with short-segment lesions, and profundoplasty may be effective in others, most patients with an ischemic limb require conventional surgical bypass. Most claudicants achieve sustained relief, and 80% to 90% of limbs threatened with critical ischemia are salvaged with vascular reconstruction. Of variables influencing the ultimate outcome, the choice of conduit is most important. For optimal results, every effort must be made to use autogenous vein for infrainguinal reconstruction (71,72).

Inframalleolar revascularization (pedal bypass grafting) has become an accepted treatment for patients with severe distal disease, limb-threatening ischemia, and tissue loss, regardless of age or diabetic status (73,74). *In situ* distal bypass using reverse or intact saphenous vein has shown promising long-term patency. Patient mortality rate following revascularization averages about 5%. Patient survival rates range from 30% to 70% at 3 years (annual mortality rate following recovery from operation is between 10% and 20%) (75). If the arterial anatomy of the foot permits, autologous vein bypass should be offered to patients with severe limb ischemia before a major amputation is considered. Pedal bypass grafting has low perioperative mortality and morbidity. Postoperative

surveillance with duplex ultrasonography is warranted to detect hemodynamically significant abnormalities within the graft that can be corrected before thrombosis occurs. With this, failing grafts can be salvaged, secondary patency can be improved, and the rate of late amputations diminished (76). Once thrombosis occurs, attempts to restore long-term patency are unlikely, and only modest limb salvage rates will be achieved. Patients with chronic renal insufficiency have been shown to have a poor outcome following re-intervention. Data suggest that re-intervention should not be considered when these patients present with failed grafts following an initial pedal bypass procedure (77,78).

Attempts at revascularization should be avoided in the presence of life-threatening sepsis, chronic flexion contracture, paralysis, and in patients with markedly reduced life expectancy. A multicenter randomized trial showed that coronary artery revascularization before elective vascular surgery does not alter long-term survival (79). Revascularization should be delayed in most individuals with a significant acute comorbidity (recent myocardial infarction) unless the limb is eminently threatened and a higher perioperative morbidity is acceptable (80).

### Intermittent Pneumatic Compression

Intermittent pneumatic foot and calf compression has been shown to improve walking distance comparable with supervised exercise (81). This may be a useful device in rehabilitation centers involved in wound management after providers are properly trained in its use. Skin blood flow, as reflected by  $TcPO_2$ , can be augmented acutely in ischemic limbs by intermittent venous occlusion with an externally applied inflatable cuff (82). External compression briefly raises the tissue pressure, emptying the underlying veins and transiently reducing the venous pressure without occluding arterial blood flow. The proposed mechanism to explain the increased flow is analogous to the pumping action of the calf muscle during walking (83). The transient inflation imitates the effects of normal gait by generating vigorous hemodynamic impulses throughout the veins each time the lower extremity is compressed. The pneumatic impulse enhances the venous return and causes venous pressure to decrease transiently until veins are refilled by forward flow from the arteries. An increase in the hydrostatic pressure gradient during this brief period is thought to be a major mechanism for the enhancement of arterial leg inflow. The altered flow and shear forces generated by the inflation of the pneumatic cuff may mediate the release of endothelial and humoral factors having local and systemic effects (83). A direct reduction in peripheral resistance is also postulated via release of nitric oxide secondary to shear stress across the vessel wall (84).

### Chelation Therapy

Given its lack of efficacy and important safety concerns, EDTA should not be used to treat patients with intermittent claudication (36). Chelation therapy with EDTA has the potential for significant and even fatal complications. Nephrotoxicity

that may produce renal failure is a recognized complication of EDTA therapy. In addition, rapid infusion of EDTA may produce hypocalcemia with resultant tetany and cardiac arrhythmias.

### Acute Arterial Occlusion

Most cases of acute arterial occlusion can be attributed to one of three causes: thrombosis, dissection, and emboli.

#### Thrombosis

Thrombosis usually occurs at the site of an underlying vascular abnormality such as an atherosclerotic lesion or an aneurysm.

#### Dissection

Dissections are associated with hypertension, atherosclerosis, connective tissue disorders, trauma, and iatrogenic causes (related to invasive diagnostic and therapeutic cardiovascular interventions) (37).

#### Emboli

Emboli sizeable enough to occlude relatively large arteries typically have a cardiac source. The most common abnormalities causing cardiac-derived emboli include ventricular mural thrombi, valvular diseases, and atrial disorders such as chronic or paroxysmal atrial fibrillation. An unusual cause of arterial embolus includes a paradoxical embolus (a DVT that passes through an atrial septal defect, ventricular septal defect, or patent foramen ovale, and enters the arterial system). In about 5% to 10% of cases, no source of emboli is found. Emboli tend to be multiple and recurrent. Certain hypercoagulable states, such as protein C and S deficiency, the presence of antiphospholipid antibody, and malignancy have been associated with peripheral embolism.

### Clinical Presentation

The clinical presentation of acute arterial occlusion is described as “six Ps”: pain, pallor, paresthesias, paralysis, pulselessness, and polar (cold). Some or all of these findings may be present. The limb is at risk if blood flow is not restored quickly. Once the tissues become ischemic, cells compensate for the lack of oxygen by converting to anaerobic metabolism. Lactic and pyruvic acids are produced and released into the circulation. If the ischemia persists, cellular adenosine triphosphate stores are depleted, and the cells swell due to their inability to maintain the sodium/potassium pump. Tissue swelling eventually overcomes the capillary filling pressure; this produces ischemia. Clinically, this phase is characterized by pain, muscular rigidity, nonpitting edema of the extremities, and metabolic acidosis. If the ischemia persists, cell membrane disruption occurs with release into the circulation of large amounts of potassium, lactic acid, myoglobin, creatinine phosphokinase, lactic dehydrogenase, serum glutamic-oxaloacetic transaminase, and glutamic-pyruvic transaminase. These findings can also be seen with reperfusion following delayed revascularization.

### Treatment of Acute Arterial Occlusion

Ideally, all acute occlusion warrants immediate repair, although the urgency is governed by the degree of ischemia. If a patient presents with symptoms consistent with the “six Ps,” a medical-surgical emergency exists, and immediate evaluation and intervention must be performed. Severe ischemia is suggested by pallor at rest, profound coolness, tender or hard muscles, and loss of motor and sensory functions. When severe ischemia is present, repair must occur within hours to salvage the limb. Immediate measures are needed to protect the lumen and restore the blood flow. The standard therapy for arterial emboli remains surgery. The most common site of embolization is the femoral bifurcation. Ideal treatment consists of expeditious diagnosis of acute arterial ischemia, recognition of the embolic source, rapid systemic anticoagulation, and surgical embolectomy. Heparin is given to prevent thrombus propagation and treat the embolic source. Angiography may be required to plan a repair when there is preexisting occlusive or aneurysmal disease, or when the etiology is uncertain. Balloon embolectomy is performed without angiography when the embolic source is certain and the vessel was previously normal. In acute arterial thrombosis, lysis of acute occlusion can be effective (85). If a thrombolytic strategy is elected, one must ensure that the infusion catheter can be positioned within the substance of the thrombus. An open operative approach is necessary when access to the thrombus cannot be achieved. Successful thrombolysis should be followed by endovascular or open surgical revision of any lesion unmasked after dissolution of the thrombus. Endovascular modalities such as balloon angioplasty with or without stenting can be performed at the conclusion of thrombolysis (usually through the same access site used for the infusion).

Historically, it has been thought that 4 to 6 hours (following the onset of symptoms) is the maximal length of tolerable ischemia. Patients with prior chronic limb ischemia tend to tolerate longer period of acute ischemia. The physiologic state of the limb, determined mainly by a balance between metabolic supply and demand, rather than the elapsed time from the onset of occlusion, is actually the best predictor of limb salvage.

### Other Arterial Diseases

#### Upper Extremity Ischemia

Symptomatic vascular diseases involving the upper extremity are rare in comparison to those involving the lower extremity. However, ischemia caused by vasospasm is much more common in the upper extremities than in the lower extremities. Upper extremity arterial occlusive disease is less common, but more varied in etiology, than disease of the lower extremity; associated vasospastic and microcirculatory disorders are more common. Coldness and color changes are the most common presenting symptoms in upper extremity ischemia. Ischemia may be constant or intermittent; a manifestation of a fixed arterial obstruction, vasospasm, or both; and it may reflect involvement of large proximal arteries, small distal arteries, or the microvasculature. Impairment of the arterial circulation

to the upper extremities may result in a variety of symptoms including weakness, intermittent vasospasm, or irreversible tissue loss with digital ulcers, skin necrosis, and gangrene.

The manifestation of acute arterial occlusion of the upper extremity depends on the location and extent of the clot, the preexisting status of the vascular bed, and the collateral flow. Occlusion of the ulnar artery may be asymptomatic if the radial and palmar arch circulation is intact. In contrast, occlusion of the axillary artery (before the bifurcation of the brachial and profunda brachial artery) will typically result in severe ischemia. Raynaud's phenomenon, connective tissue disease, vasculitis, thromboangiitis obliterans (Buerger's disease), erythromelalgia, acrocyanosis, livedo reticularis, pernio, frost bite, and occupational trauma may result in microvascular disease of the upper extremity (37). Arteriolar constriction is usually well tolerated. When arteriolar constriction is superimposed on fixed arterial obstruction, previously viable fingers may become ischemic.

Establishing the underlying etiology is essential for both definitive treatment and the prognosis of the patient. Upper extremity ischemia may cause a significant impairment due to decreased hand function.

### Raynaud's Syndrome

Raynaud's syndrome is characterized by episodic attacks of vasospasm in response to cold or emotional stress. The fingers and hands are most often affected. In certain patients, the toes and feet may be involved. Classic episodes of vasospasm cause an intense pallor of the distal extremity followed in sequence by cyanosis and rubor on rewarming. Most patients do not experience the complete triple color response. Typically, only pallor or cyanosis is noted during attacks. Generally, the attacks are over within 30 to 60 minutes. Episodes are usually bilateral. Attacks may occur infrequently, for example, some may only have symptoms during the winter, but other patients may have a significant impairment/disability with multiple daily episodes. Digital ulcerations are rare but may occur. Females are affected more commonly than males. The mechanisms responsible for episodes of digital vasospasm remain an enigma. The symptoms may be related to abnormalities in adrenergic function, blood viscosity, or endothelial disorders (86). The normal regulation of blood flow to the fingers is affected by a number of different factors acting by local, humeral, and nervous mechanisms. Disturbance of any of these may predispose to vasospastic attacks in primary Raynaud's. The exact mechanism of digital artery vasospasm in Raynaud's syndrome remains unknown; however, it is felt to be due to an exaggeration of the normal thermoregulatory system. In clinical practice, it is helpful to differentiate patients with Raynaud's syndrome as having either vasospasm or obstructive disease.

Raynaud's disease refers to a primary vasospastic disorder where there is no identifiable underlying cause. Raynaud's phenomenon refers to vasospasm, secondary to another underlying condition or disease. Predisposing factors include atherosclerosis, arteritis, cancer, collagen vascular disease, thoracic outlet syndrome, embolic occlusion, occupational

disease, and certain medications (86). Secondary Raynaud's phenomenon is occasionally unilateral and may produce skin breakdown. The distinction between Raynaud's disease and Raynaud's phenomenon has important clinical utility as it underscores the different pathologic mechanisms, treatment options, and outcomes of these two groups.

### Treatment

Treatment of primary Raynaud's syndrome may be difficult. Fortunately, the majority of patients with Raynaud's disease have only mild to moderate symptoms that respond well to conservative measures. Dressing warmly, using mittens rather than gloves, heat conservation, and avoiding unnecessary cold exposure may substantially improve symptoms. Nicotine and drugs with a potential for vasoconstriction should be avoided. Biofeedback is effective in certain cases. If a secondary cause of vasospasm is not identified, often reassurance and patient education are all that is necessary. Occasionally, it is necessary for a patient to move to a warmer climate to achieve complete relief.

Pharmacologic therapy is indicated for patients with severe symptoms whose activities of daily living are affected or those who are at risk of ischemic tissue damage. A number of vasodilator medications have proved to be beneficial for patients with Raynaud's syndrome. Calcium channel blockers are the most commonly prescribed medications for vasospasm associated with Raynaud's syndrome. Multiple studies have shown dihydropyridines, such as Nifedipine, to be effective in reducing the frequency and severity of vasospastic attacks. Alpha-1 blockers such as doxazosin and terazosin may also be of benefit in reducing the frequency and severity of attacks. Angiotensin-converting inhibitors and angiotensin-II receptor antagonists may be of benefit in both primary and secondary Raynaud's (86).

Novel therapies for Raynaud's syndrome with upper extremity ischemia refractory to standard therapy include: (a) prostacyclin administered as a continuous intravenous infusion; (b) a potent endothelial-derived endothelin blocker Bosentan; and (c) an intermittent pneumatic compression (87). Interruption of the sympathetic innervation, either through ganglionic injection or surgical sympathectomy, is reserved for patients with severe symptoms.

### Vasculitic Syndrome

Vasculitis, or angiitis, is an inflammatory disease of blood vessels. It often causes damage to the vessel wall, stenosis or occlusion of the vessel lumen by thrombosis, and progressive intimal proliferation. Vasculitic symptoms reflect systemic inflammation and the ischemic consequences of vascular occlusion. The distribution of vascular lesions and the size of the blood vessels involved vary considerably in different vasculitic syndromes and in different patients with the same syndrome. Vasculitis can be transient, chronic, self-limited, or progressive. It can be the primary abnormality or secondary to another systemic process. Histopathologic classification does not distinguish local from systemic illness or secondary from primary insult.

**FIGURE 45-5.** Small vessel ischemic/pressure wound in a patient with rheumatoid arthritis.

### ***Rheumatoid Vasculitis***

Rheumatoid vasculitis usually occurs in patients who have severe deforming arthritis and a high titer of rheumatoid factor (88). The vasculitis is mediated by the deposition of circulating immune complexes on the blood vessel wall with activation of complement. Proliferation of the vascular intima and media causes an obliterative endarteropathy. Leukocytoclastic, or small vessel vasculitis, produces palpable purpura or cutaneous ulceration (Fig. 45-5). A systemic necrotizing vasculitis, histopathologically indistinguishable from polyarteritis nodosa (PAN), complicates some cases of seropositive rheumatoid arthritis. Rheumatoid arthritis–associated polyarteritis is three times as common as primary polyarteritis. Type II cryoglobulin and vasculitis may complicate many different connective tissue diseases. Cryoglobulin should be assayed in any patient with an autoimmune disease that develops vasculitis (88).

### ***Cryoglobulinemia***

Cryoglobulins are immunoglobulins that reversibly precipitate at reduced temperatures. Type I cryoglobulins are aggregates of a single monoclonal immunoglobulin. Patients with type I cryoglobulinemia are often asymptomatic. Type II cryoglobulins are frequently associated with chronic infection (hepatitis C) and immune disorders. The typical presentation of type II cryoglobulinemia is that of a nonsystemic small vessel vasculitis with palpable purpura, urticaria, and cutaneous ulceration. Peripheral neuropathy, arthralgias, and arthritis are common.

### ***Polyarteritis***

Polyarteritis occurs by itself (PAN) or in association with another disease (secondary polyarteritis). PAN is an acute necrotizing vasculitis that affects primarily medium-sized and small arteries. It is a systemic disorder that may involve the kidneys, joints, skin, nerves, and various other tissues. Biopsy typically shows necrotizing changes and disruption of the blood vessels (89). If untreated, the systemic form of PAN is associated with

a less than 15% survival rate at 5 years. With steroid therapy, the 5-year survival rate increases to more than 50% (89).

### ***Other Vasculitides***

A wide variety of other vasculitides may affect small and medium-size vessels. These include allergic angiitis (Churg-Strauss syndrome), Henoch-Schönlein purpura, various forms of hypersensitivity vasculitis, and numerous nonspecific necrotizing and nonnecrotizing vasculitides. Knowledge of the etiology of an underlying vasculitis is critical for rehabilitation professionals involved in the management of ischemic wounds.

### ***Treatment***

General measures should be performed as outlined for patients with PAD. In addition, because vasculitic processes typically involve small vessels (arterioles, venules), gentle compression with a low-stretch wrap or graduated compression stockings (20 to 30 mm Hg) may decrease associated venous congestion and enhance skin perfusion.

### ***Thromboangiitis Obliterans (Buerger's Disease)***

Thromboangiitis obliterans (Buerger's disease) is a segmental disease of the arteries and veins of the extremity. The first manifestation of Buerger's disease may be superficial phlebitis. Thromboangiitis obliterans occurs predominantly in young adult male smokers. Few, if any, cases occur in the absence of tobacco use. If smoking is discontinued, the process is frequently arrested.

There are two major distinguishing features of Buerger's disease compared with other forms of vasculitis. Pathologically, the thrombus is highly cellular, with relative sparing (less intense cellular activity) in the wall of the blood vessel. The disease usually affects the small distal arteries first and progresses proximally if smoking continues (90). In addition, the usual immunologic markers (sedimentation rate and CRP, circulating immune complexes, antinuclear antibody, rheumatoid factor, and complement) are usually normal or negative. It is not known whether the vascular lesions of Buerger's disease are primarily thrombotic or inflammatory. In either case, the intense inflammatory infiltration and cellular proliferation seen in the acute-stage lesions are distinctive, especially when the veins are involved. Buerger's disease is segmental in distribution. "Skip" areas of normal vessel between diseased segments are common. The intensity of the periadventitial reaction may be quite variable in different segments of the same vessel. The skip lesions may be observed angiographically and histopathologically (91).

### ***Treatment***

Cessation of smoking is an absolute necessity. Other treatments such as antiplatelet therapy and sympathectomy are of variable benefit.

### ***Thoracic Outlet Syndrome***

Thoracic outlet syndrome occurs when the brachial plexus, subclavian artery, or subclavian vein become compressed in

the region of the thoracic outlet. Symptoms are thought to result from nerve compression in 90% to 95% of cases (92). The second most common presentation is venous compression. Repetitive trauma to the artery can lead to intimal damage, embolization, aneurysm formation, or acute thrombosis. Although only a small number of cases of thoracic outlet syndrome are clearly due to arterial compression, thoracic outlet syndrome is the most common cause of acute arterial occlusion in the upper extremity of adults younger than 40 years old and the most common cause of acute upper extremity venous occlusion in the young adult. The cause of arterial thoracic outlet syndrome is often a cervical or rudimentary first rib. Primary venous thoracic outlet syndrome is generally due to the costoclavicular ligament and subclavius muscle compressing the subclavian vein. Arterial involvement is suggested by obliteration of the radial or brachial pulse during provocative maneuvers of the arm (this finding may also be a normal variant). One of the most useful clinical tests is the elevation arm stress test. A patient raises his or her hands above the head and clenches and unclenches the fist for 1 or 2 minutes. The appearance of the patient's typical symptoms with or without signs of vascular involvement (delayed capillary refilling) is suggestive of this syndrome. Duplex ultrasound or arteriography can be used to document the presence of a functional hemodynamic change with thoracic outlet maneuvers.

### **Treatment**

Nonsurgical measures, including stretching (scalenes, pectorals, and trapezius muscle) without recreating symptoms, positioning, and avoidance of aggravating factors may be of benefit. If nonsurgical measures fail and symptoms warrant, surgical resection of the first rib is frequently curative. In those with significant arterial involvement (such as intimal damage or aneurysmal formation), the involved section of artery should be replaced with a graft. Advances in the management of arterial and venous complications include thrombolysis, mechanical thrombectomy, and endovascular stenting. Patients with recent venous thrombosis can have the thrombus cleared with thrombolytic therapy before rib resection. Stenting, if needed, is performed after removal of the first rib and should not be applied if the first rib has not been resected.

### **Giant Cell Arteritis**

Giant cell arteritis often involves the arch, thoracic, and abdominal aorta as well as proximal branch artery.

### **Temporal Arteritis**

Temporal arteritis affects older individuals and involves branches of the external carotid, brachial, and femoral arteries. Temporal arteritis primarily affects people older than 50 years (93). It predominantly involves secondary or tertiary branches from the aorta. Only about 50% of persons with temporal arteritis have headache or tender temporal arteries. Common symptoms include low-grade fever, jaw claudication, weight loss, anorexia, and other systemic symptoms (93). The erythrocyte sedimentation rate is usually elevated.

In an elderly person with a new onset of mild to moderate temporal headache, temporal arteritis should be considered. If vision loss has already occurred, emergent therapy with corticosteroids is needed. In those with no vision loss, prednisone should be initiated immediately after the diagnosis is made. Temporal biopsy is used to confirm the diagnosis before prescribing long-term prednisone therapy. If the biopsy cannot be performed immediately, prednisone therapy may be initiated until biopsy results are available. High-dose prednisone (40 to 60 mg/daily initially) is usually instituted for 3 to 6 weeks or until the sedimentation rate has stabilized in the normal range. Biopsy results remain accurate, if the biopsy is performed within several days after starting treatment with corticosteroids. Immune-modifying agents may decrease the complications of prolonged steroid suppression. The rate of steroid taper should be modified according to the sedimentation rate and the clinical picture. When surgical correction is necessary, efforts should be made to hold off until the disease has been adequately treated, or preferably until it has "burned out." Although angiography can be used to make the diagnosis, biopsy is much more commonly used because of accessibility of the temporal artery. Advances in noninvasive imaging (CT and MR angiography) have increased their diagnostic accuracy and provide a marker to follow disease progression.

### **Vibration Syndrome**

Vibratory tools such as chain saws, grinders, and jackhammers can induce hand dysesthesias and Raynaud's phenomenon when used for several years. Symptoms initially occur during use of the instrument. Subsequently, dysesthesias and cold sensitivity persist when the vibratory tool is not being used. After several years, a late stage can be seen with frank digital artery occlusion, cyanosis, ulceration, and gangrene. Ischemia is a rare and late occurrence (94). The exact mechanism of injury is unknown. Repetitive trauma from the vibration of tools is obviously the main cause of the problem. Both the frequency of the vibration and the intensity of the trauma it produces affect the extent of damage to the endothelium (95).

### **Treatment**

The treatment of vibration injuries include simple measures and medications outlined for the treatment of Raynaud's phenomenon. In addition, vibration gloves and modifications to decrease vibratory trauma may be of benefit.

### **Hypothenar Hammer Syndrome**

Occlusive disease in the hands can result from trauma to the hypothenar area caused by using the palm of the hand as a hammer in an activity that involves pushing, pounding, or twisting. This results in intimal injury to the ulnar artery as it crosses the hamate bone. When this area is repeatedly traumatized, ulnar or digital arterial spasm, aneurysm, occlusion, or a combination of these lesions can result. This may result in Raynaud's phenomenon and digital ischemia as the artery either becomes aneurysmal and embolizes or occludes (96).

### External Iliac Syndrome in Cyclists

Cyclists with high-level training and competition over several years may report claudication (typically, buttock and thigh) followed by heaviness or numbness of the limb. The symptoms often occur under maximal stress (hill climbing or sprinting) with quick relief as the pace is reduced. Pulse and ankle systolic pressures are normal at rest, but drop when symptoms are reproduced by strenuous ergometric cycling. The history and clinical findings are compatible with subclinical stenosis that becomes hemodynamically significant with maximal stress. Surgical repair includes segmental resection to shorten the artery, endarterectomy, and ligation of a prominent psoas arterial branch (that may enhance arterial lengthening) when present (97).

## VENOUS DISEASE

### Thrombophilia

Thrombophilia is a hereditary or acquired disorder predisposing to thrombosis.

### Deep Vein Thrombosis

DVT is a serious medical condition that continues to plague immobilized patients and those rehabilitation professionals who care for them. The incidence of venous thromboembolism exceeds 1/1,000 (98). Of all venous thromboembolism patients, 30% die within 30 days (99). When a patient presents with the possibility of a DVT, predisposing risk factors such as prolonged immobilization during car or plane trips, use of estrogen, prior DVT, or family history of thrombosis should be elicited. Hypercoagulable states such as those associated with cancer or inherited coagulopathies and those caused by vessel wall injury from surgery or local trauma are major predisposing factors for thrombosis. About 30% of surviving cases develop recurrent venous thromboembolism within 10 years. Independent predictors for recurrence include increasing age, obesity, malignant neoplasm, and extremity paresis. About 28% of patients develop venous stasis syndrome within 20 years. To reduce venous thromboembolism incidence, improve survival, and prevent recurrence and complications, patients with these characteristics should receive appropriate prophylaxis (100).

As initially postulated by Virchow, three factors are of primary importance in the development of venous thrombosis: (a) abnormalities of blood flow (especially reduced flow, or *stasis*), (b) abnormalities of blood, and (c) vessel wall injury.

The normal hemostatic response requires interactions among the vessel wall, endothelium, platelets, and the coagulation cascade responsible for thrombin generation. Early phases of thrombosis are marked by increases in permeability followed by leukocyte adhesion, migration, and endothelial disruption (101). Stasis may facilitate endothelial leukocyte adhesion and cause endothelial hypoxia leading to a procoagulant state. In addition, stasis allows the accumulation of activated coagulation factors in areas prone to thrombosis.

Although the hemostatic system is continuously active, thrombus formation is generally confined to sites of local injury by a precise balance between activators and inhibitors of coagulation and fibrinolysis. A prothrombotic state may result from imbalances in the regulatory and inhibitory system or from activation exceeding antithrombotic capacity (102).

Thrombosis may occur anywhere but most commonly involves the deep veins of the leg. Once a thrombus forms, several events may occur: (a) the thrombus may propagate, (b) it may embolize, (c) it may be removed by fibrinolytic activity, or (d) it may undergo organization (including recanalization and retraction). An initial inflammatory response leads to fibroblast and capillary ingrowth, which helps to stabilize the thrombus. Organization occurs over weeks to months as the thrombus becomes incorporated into the vessel wall. Once luminal flow is disturbed, prograde and retrograde propagation of the thrombus may also be promoted by hemodynamic factors. The competing processes of recanalization and recurrent thrombosis determine the extent of acute DVT and its sequelae. Venous thrombi rarely lyse completely unless they are subjected to pharmacologic lysis.

The natural history and clinical consequences of a lower extremity venous thrombosis depend on the site of thrombus. Because the tibial and peroneal veins run in parallel, a thrombosis confined to one of these veins is unlikely to cause significant obstruction to the outflow of blood. Small calf vein thrombi frequently occur, especially in postoperative patients. Of those that are asymptomatic, half lyse spontaneously and are unlikely to proceed to deep vein incompetence (103). A calf thrombosis may remain asymptomatic; the thrombus often dissolves without sequelae by natural fibrinolysis. Five to 20% of calf vein thrombi propagate proximally. If extension occurs into the popliteal or more proximal veins, the chance of pulmonary embolism increases from less than 5% to about 50% (104). Thrombus isolated to the calf is less dangerous than thrombus in the thigh, but greater than 20% of such thrombi can extend proximally, and 10% embolize. Laboratory surveillance of lesions is required if anticoagulants are not used (105). Thrombi involving the proximal veins are less likely to undergo spontaneous lysis, even with heparin therapy.

### Treatment

#### Medical

Superficial thrombophlebitis is treated with elevation and superficial heat. Compression wraps or stockings should be worn when ambulating. However, if the thrombotic process is close to the saphenofemoral junction, vascular surgery consultation is warranted for possible high ligation of the saphenofemoral junction.

Standard therapy of acute DVT consists of anticoagulation, elevation, and support of the extremity. Of primary importance is the prevention of thrombosis, with recognition of high-risk groups and effective prophylaxis of thromboembolic disease.

### Anticoagulants

Anticoagulants remain the main form of treatment for thromboembolic disease. The two goals of anticoagulation in DVT are to prevent death from pulmonary embolism and to limit venous damage and subsequent postphlebitic syndrome. Prophylactic anticoagulation is warranted in patients with prior venous thromboembolism or known clotting disorders that are traumatized or undergo medical or surgical treatments with prolonged bed rest. If anticoagulation must be interrupted for a surgical procedure, baseline duplex ultrasound and surveillance ultrasounds (every 3 to 5 days) should be obtained.

**Heparin.** Heparin anticoagulation has been well documented as an effective treatment for thromboembolic disease. Although heparin has no fibrinolytic activity, it allows natural fibrinolysis, which stabilizes the thrombus, avoids further propagation, and relieves acute symptoms in most patients.

Early complications with heparin include thrombocytopenia. Benign thrombocytopenia is a common occurrence (platelet counts dropping to 70,000 to 100,000 units/L). Rarely, a severe antibody-mediated thrombocytopenia occurs that may predispose to further thrombosis. In these patients, heparin should be stopped immediately. Heparin-induced thrombocytopenia (HIT) is more common with bovine heparin and less common with prophylactic doses or low-molecular-weight heparin (LMWH). Thrombocytopenia may occur 3 to 15 days after the initiation of heparin therapy. Acceptable non-Heparin anticoagulants include Lepirudin or argatroban. Because of significant cross-reactivity, LMWH is not an acceptable alternative for these patients. Removing Heparin alone is not sufficient to prevent the thrombotic complications of thrombocytopenia (HIT). Immediate substitution of Warfarin for Heparin can result in disastrous complications such as venous limb gangrene, skin necrosis, or worsening of a preexisting thrombosis (106).

**LMWH.** Comparing the safety and efficacy of LMWH with standard heparin in the treatment of acute proximal DVT, the differences between the groups in recurrent thrombosis, major bleeding, or mortality was not significant (107). LMWH has much less nonspecific binding to plasma proteins, improved bioavailability, and more predictable pharmacokinetics. LMWH dosage is based on patient body weight. Activated partial thromboplastin time monitoring is neither required nor useful. Patients with acute proximal DVT can be treated safely and effectively with LMWH at home during the initiation of warfarin therapy. Consistent evidence demonstrates that LMWH is superior to unfractionated Heparin for the initial treatment of DVT, particularly for reducing mortality and reducing the risk for major bleeding during initial therapy. Additional trials are needed to more rigorously examine the efficacy of LMWH for the initial treatment of pulmonary embolism, but systematic reviews of existing trials indicate that LMWH is at least as effective as unfractionated Heparin for these patients as well (108).

LMWH is an option for patients in whom INR control is difficult, and it may be more efficacious than oral anticoagulants in patients with cancer (109).

**Warfarin.** Warfarin (Coumadin) acts to inhibit the liver synthesis of vitamin K-dependent coagulation factors II, VII, IX, and X. The effect is delayed until these coagulation factors are cleared from the circulation. Factor VII has the shortest half-life (7 hours), resulting in a prolongation of the prothrombin time. Coagulation is not inhibited until other clotting factors are depleted. The American College of Chest Physicians recommends starting Warfarin with unfractionated Heparin or LMWH for at least 5 days and continuing until a therapeutic INR is achieved (110).

Warfarin also depletes natural inhibitors of coagulation, including protein C and protein S. A rare complication of warfarin therapy is skin necrosis. This has been noted in some patients with protein C deficiency. Hemorrhagic skin necrosis often involves areas where there is extensive adipose tissue (breast, buttock, thigh, or abdominal wall) and may be due to small vessel thrombosis, perhaps related to the reduction of protein C by warfarin. Gradual initiation of warfarin may prevent an abrupt drop in protein C levels.

Warfarin is contraindicated in the first trimester of pregnancy because of teratogenic effects and during the third trimester because of an increased risk for bleeding during delivery.

### Thrombolytic Agents

Thrombolytic agents (streptokinase, urokinase, and tissue plasminogen activating factor) rapidly dissolve fresh (<1 week old) clots and may restore patency of the obstructed vein. Thrombolytic agents are not used routinely but may be indicated in the case of a massive proximal DVT. Thrombolysis should be considered for all patients presenting with acute DVT of the ilio caval vein (111). Thrombolysis should also be considered for young, otherwise healthy patients with extensive proximal thrombosis and threat of permanent impairment (104). After experimental acute DVT, thrombolytic therapy and balloon-catheter thrombectomy at 3 hours had similar effects on the valvular competence and the endothelial morphology. In addition, the thrombolytic therapy preserved endothelial responses to platelet products. The data suggest that thrombolytic therapy may preserve vein function after DVT and reduce the long-term potential for recurrent DVT and postthrombotic syndrome (112). If venous insufficiency develops, treatment should proceed as outlined in the section on chronic venous insufficiency.

### Vena Cava Filters

Vena cava filters are indicated to prevent pulmonary embolism in patients with a venous thromboembolism who have a contraindication to anticoagulation, failed anticoagulation, VTE during pregnancy, preoperative prophylaxis, bariatric surgery, multitrauma, neurosurgery, or orthopedic surgery with a recent DVT (1 month). Anticoagulation should be considered when the temporary contraindication to anticoagulation therapy is no longer present. There is insufficient data to support a recommendation that all filter recipients should be treated with indefinite anticoagulation regardless of the risk of recurrent

thrombosis. Until recently, all vena cava filters were permanent implants. There are now filters available that can be removed when the thrombosis risk is over or when anticoagulation can be initiated.

### *Phlegmasia Cerulea Dolens*

Phlegmasia cerulea dolens is a rare complication of DVT, characterized by rapid and massive edema, severe pain, and cyanosis (104). Distal cyanosis may indicate extensive blockage to venous return. Phlegmasia cerulea dolens most commonly occurs with proximal, iliofemoral obstruction with extensive distal thrombus of deep and superficial veins. In phlegmasia, the arterial pulses may not be palpable, although anatomically, the arteries are patent. In severe cases, gangrene, which may necessitate amputation, occurs (104). Urgent treatment, including placement of a caval filter, heparinization, and surgical thrombectomy or thrombolysis if possible, is essential to minimize loss of life or limb. Thrombolytic therapy is often given from both the venous and arterial side.

### Chronic Venous Insufficiency

Chronic venous disease is an important cause of discomfort and disability, and is present in a significant percentage of the population worldwide. A clinical score of Clinical-Etiologic-Anatomic-Pathophysiologic has been developed as a standard for reporting venous disease (113).

Many factors can result in the development of venous insufficiency, including heredity, local trauma, thrombosis, and intrinsic defects in the veins or valves themselves. Venous flow is based on a force that pushes the blood proximally, an adequate outflow, and the presence of competent valves limiting reflux. Any disruption of these components results in chronic venous hypertension (114). Normally, the pressure in the leg veins is equal to the hydrostatic pressure from a vertical column of blood extending to the right atrium of the heart. At the ankle level, the hydrostatic pressure is about 90 mm Hg (115). The pumping action of the calf muscles during exercise reduces this venous pressure by two thirds. Even slight muscular movements during normal standing will lower the pressure (115). Patients with venous insufficiency might fail to reduce ankle pressure or show a rapid return of venous pressure to resting levels at the end of exercise. The time required for the ankle vein pressure to return to resting levels after exercise is an indicator of the degree of reflux in the limb. Elevated ambulatory venous pressure is associated with an increased incidence of ulceration (116). When ambulatory venous ankle pressure is below 30 mm Hg, the incidence of ulceration is close to 0%. The incidence of ulceration increases linearly, reaching 100% when the ambulatory venous pressure is greater than 90 mm Hg (116). The superficial leg veins normally carry 10% to 15% of the venous return. Incompetent valves in the superficial veins alone rarely cause serious venous hypertension, although 10% of patients with venous ulcers have superficial venous incompetence alone.

Postthrombotic syndrome (venous occlusion or valve destruction after thrombosis) develops in 67% to 80% of

**FIGURE 45-6.** Chronic venous insufficiency with edema, increased pigmentation, induration, dermatitis, and ulceration.

patients after DVT, although ulcers form in less than 5% of the patients (117). Venous insufficiency may present up to 5 to 10 years after the resolution of the acute episode of thrombosis. Postthrombotic damage in the deep veins is an important cause of chronic venous insufficiency. Advanced venous insufficiency develops only when the valves in the perforator or deep veins are also incompetent. Ultimately, venous hypertension is the result of valve damage and retrograde venous blood flow to the superficial veins. The true mechanism by which venous hypertension leads to induration and fibrosis of the skin (lipodermatosclerosis) and ulceration (Fig. 45-6) remains unclear (118).

### Treatment

Because venous hypertension in the upright position and during ambulation is the physiologic cause of the damage in chronic venous insufficiency, the first step of treatment should be to reduce the ambulatory venous pressure. Compression therapy is the mainstay of treatment for chronic venous insufficiency.

### Rehabilitation

**Compression.** To prevent postthrombotic syndrome, compression stockings should be used routinely following diagnosis of a proximal DVT and continued for a minimum of 1 year (108). Compressive dressings aid venous return by compressing the leg and increasing the interstitial tension. Compression of dilated, engorged, superficial, and intramuscular veins indirectly increases the efficiency of the calf pump mechanism (115). With no history of congestive heart failure and no evidence of venous obstruction (on noninvasive studies), lower extremity volume can be stabilized with an intermittent pneumatic compression pump (40 to 50 mm Hg). Compression wraps should be used between pumping sessions. After the volume stabilizes, the patient can be measured for stockings. Elastic stockings should provide graduated compression, exerting most pressure at the ankle, less at the

calf, and least pressure at the thigh. Typically, knee-length graduated compression stockings with a pressure of 30 to 40 mm Hg (at the ankles) are prescribed. When elevation is used for edema control, the extremity is typically elevated above the level of the heart. The patient should lie on a sofa or sit in a recliner to elevate the legs appropriately. The correct duration and frequency of leg elevation should be tailored to the severity of disease. The leg should be elevated whenever possible and long periods of standing or sitting should be avoided. In patients with concomitant arterial disease, lower compression and modified elevation is used to avoid further compromise of arterial inflow.

**Exercise.** The value of exercise in the management of chronic venous insufficiency has not been conclusively demonstrated. Exercises involving the leg musculature, such as walking, bicycling, or swimming, promote muscle tone in the calf and enhance venous return. Exercise, however, produces variable reductions in venous hypertension. Patients with chronic venous stasis due to incompetent deep vein valves generally do not obtain as much reduction in venous pressure as do those in which the primary defect is due to incompetent perforator valves (119).

**Sclerotherapy.** Sclerotherapy (which uses the injection of an irritant substance into the vein) can be used to obliterate incompetent veins in certain settings (114,120). Sclerotherapy is used for the treatment of spider veins, small distal varicose veins, and venous insufficiency resulting from superficial and perforator incompetence. Ultrasound-guided sclerotherapy has been used successfully to treat incompetent perforator veins (121). Complications are rare, usually minor and include skin discoloration, thrombophlebitis, and hematoma formation. The temporary use of elastic compression is suggested after treatment.

### **Surgery**

Ablation of superficial reflux is performed by stripping, radiofrequency or endovenous laser therapy of the greater saphenous vein, and avulsion of varicose veins. Subfascial endoscopic perforator vein surgery (SEPS) is included for patients with documented perforator incompetence and severe symptoms of venous hypertension. The stripping of superficial veins and SEPS should be avoided if extensive deep venous obstruction is present because the superficial veins may be acting as collaterals.

**Subfascial endoscopic perforator vein surgery.** SEPS is a minimally invasive technique performed in patients with advanced chronic venous insufficiency. The objective of the operation is to interrupt incompetent medial calf perforating veins to decrease venous reflux and reduce ambulatory venous hypertension in critical areas above the ankle where venous ulcers most frequently develop. Patients with stasis skin changes and healed or active venous ulcerations are potential candidates for the operation (122). Patients with ulcers caused by a primary valvular incompetence of the superficial and perforating veins, with or without deep vein incompetence are most likely to benefit from SEPS. These patients derive maximum

benefit in terms of accelerated ulcer healing and 80% to 90% freedom from ulcer recurrence in the long term (122). Despite improved symptoms and objective clinical scores, only 50% of patients with postthrombotic syndrome will remain free of ulcer recurrence in the long term and the role of SEPS continues to be controversial in these patients. Patients with ulcer recurrence after SEPS should undergo duplex scanning to exclude recurrent or persistent perforators (122).

**Deep vein reconstruction.** Surgical bypass should be considered in patients with iliac or iliofemoral venous occlusion. Deep vein valve repair or valve transplantation can be attempted in patients with valvular incompetence and venous ulcers. Stenting of the iliofemoral veins and inferior vena cava has emerged as the preferred treatment of venous outflow obstruction. Severe (>50%) in-stent recurrent stenosis of iliofemoral venous stents is uncommon over the short term (123).

### **May-Thurner Syndrome**

May-Thurner syndrome is defined as isolated left lower extremity swelling due to compression of the left iliac vein by the right common iliac artery. Treatment of May-Thurner syndrome has historically involved anticoagulation therapy. Advances in interventional management have allowed relief of the associated mechanical compression by open surgical or endovascular repair. Endovascular stents are the most common treatment.

## **LYMPHATIC DISEASE**

### **The Lymphatic System**

The management of lymphedema is a challenge for physicians and therapists. This component of the vascular system is often neglected in medical school curricula, yet malfunction can cause significant physiologic and functional impairment. It is important for the practitioner to have an in-depth understanding of the physiology of the lymphatic system and the pathophysiologic mechanisms of impairment to optimize management.

The lymphatic system is a vascular system composed of endothelial-lined channels that parallel the arterial and venous systems. The lymphatics originate in the tissue interstitium as specialized capillaries. These capillaries are porous and readily permit the entry of even large macromolecules such as albumin (124). The distribution of fluid between the peripheral vascular system and the tissues depends on the transcapillary balance between hydrostatic and protein osmotic pressure gradients. Normally, there is a slight hydrodynamic imbalance favoring a small amount of excess capillary filtrate (fluid, salt, and macromolecules) into the tissue spaces. This filtrate or lymph is collected by the lymphatics and returned to the venous circulation. A primary function of the lymphatic system is to return not only fluid, but also high-molecular-weight substances such as protein and particulate matter that are unable to reenter the venules or capillaries. The lymphatic system serves as a buffer system to decrease edema during fluid overload. As interstitial

fluid volume increases, interstitial fluid pressure increases. This results in a marked increase in local lymph flow (125).

### Chronic Lymphedema

The volume of lymph formed depends largely on the balance between intravascular and extravascular hydrostatic forces, osmotic forces, and the permeability of the filtering capillaries (126). Because peripheral capillaries are not readily permeable to protein, a relatively steep protein osmotic gradient between plasma and interstitium is maintained. The amount of fluid not reabsorbed constitutes the lymphatic load.

When lymphatic blockage occurs (e.g., after lymphadenectomy or radiation-induced lymph node fibrosis), intralymphatic pressure distal to the site of the blockage increases. As lymphatic vessels dilate, their valves become incompetent. Increased intralymphatic pressure also decreases lymph formation and increases tissue fluid volume.

Lymphedema may be categorized as either high-lymph-output failure or low-lymph-output failure. High-lymph-output failure results from an overproduction of capillary filtrate (congestive heart failure, ascites, nephrotic syndrome) and leads to a greatly expanded extracellular fluid space. Low-lymph-output failure (decreased lymph absorption) occurs with deficient or obliterated lymphatics.

There is a strong association between the high protein content of lymph and the proliferation of fibroconnective tissue. It has been postulated that fibrin or other specialized protein complexes dispersed throughout the interstitial matrix form an intricate lattice template facilitating the deposition of collagen (127). Fibrosis may also result from the inability of local macrophages to digest the excessive protein load (128). The accumulation of protein promotes chronic inflammation and scar formation even in conditions of adequate lymphatic drainage and normal capillary permeability (129). Although the exact mechanism of this scarring is unknown, interstitial fibrosis results in the brawny, nonpitting soft tissue swelling seen in chronic lymphedema.

### Classification of Lymphedema

Clinical lymphedema is classified as either primary or secondary (Table 45-3). Primary lymphedema occurs with aplasia, hypoplasia, or abnormal development of the lymphatic system; in addition, primary fibrosis of the lymphatics during puberty or at a later age also results in primary lymphedema. Congenital lymphedema is usually observed at birth with asymmetric presentation in a lower extremity. Several forms of heritable primary lymphedema are presently recognized (130). Milroy's disease is a familial form of lymphedema present at birth (131,132), which has been found to be autosomal dominant (131). Lymphedema praecox, typically presenting at the time of puberty, can occur anytime from the early teenage years into the third decade. Lymphedema tarda is defined as primary edema occurring after the mid-30s (133). Secondary lymphedema occurs much more commonly. Disrupted lymphatic flow may occur because of infection, trauma, tumor obstruction, surgery, or radiation. Secondary lymphedema

**TABLE 45.3 Classification of Lymphedema**

- |   |
|---|
| I. Primary lymphedema                         |
| A. Congenital                                 |
| 1. Nonfamilial                                |
| 2. Familial (Milroy's disease)                |
| B. Praecox (adolescence to about 35 y of age) |
| 1. Nonfamilial                                |
| 2. Familial (Meige's disease)                 |
| C. Tarda (onset after 35 y of age)            |
| II. Secondary lymphedema                      |
| A. Filariasis                                 |
| B. Lymph node excision &pm; radiation         |
| C. Tumor invasion                             |
| D. Other infection                            |
| E. Trauma                                     |
| F. Other                                      |

from filariasis, usually affecting the lower extremities, is the most common cause of lymphedema worldwide (134). Postsurgical compost radiation upper extremity lymphedema is the most common, with an incidence of approximately 25% (135).

Lymphedema may also be classified into clinical stages. Grade I edema easily pits in response to pressure and is reduced in response to elevation. There is no evidence of thickened spongy fibrosis on examination. Grade II edema does not easily pit with pressure and does not reduce with elevation. Some degree of fibrosis may be present. Grade III edema is irreversible with fibrosis and sclerosis of the skin and subcutaneous tissues. This severe, organized tissue change is often not responsive to mechanical treatment measures (136). Secondary lymphedema commonly presents within the first year after surgery, but can also present many years later (135). In recent years there has been recognition of a fourth grade of lymphedema termed "Grade 0." This grade refers to a latent or subclinical condition where swelling is not evident despite impaired lymph transport. It may exist months or years before overt edema occurs (137).

### Clinical Presentation

The differential diagnosis for new-onset unilateral limb lymphedema is important. Acute DVT must be ruled out whether the edema is presenting in the upper or lower extremity (see "Diagnostic Tests"). Other possibilities for diagnosis include postphlebotic syndrome, chronic venous insufficiency, tumor obstruction, chronic infection, and lipedema. Edema secondary to deep thrombophlebitis usually develops suddenly. Chronic venous insufficiency is generally associated with slowly progressing edema. Lymphedema may develop with either of these presentations. Systemic reasons for edema accumulation such as congestive heart failure, liver or renal disease, and fluid-retaining medications such as anti-inflammatory drugs and some antihypertensives should be considered.

The patient with lymphedema usually presents with asymmetric nonpainful swelling of one or both limbs. The edema often is pitting in its early stages, reduces overnight, and can exhibit a very light pinkish change in color. Chronic lymphedema does not resolve overnight and does not pit. Unlike venous edema, there is often involvement of the foot and toes with loss of dorsal vascular and joint markings. Long-standing edema leads to lymphatic stasis with inflammation and resultant hyperkeratosis with verruca-like appearance and eventual development of papillomas (138). Because the vascularity and elasticity of the skin tissues are retained in early lymphedema, the ulcerations observed in venous disease are usually absent (139). In the postsurgical breast cancer patients, presentation may include edema of the breast, chest wall, and axillary area, as well as, isolated proximal or distal extremity edema.

### Treatment of Lymphedema

Lymphedema treatment is directed at minimizing the swelling and restoring normal function and avoidance of infection of the affected region (Fig. 45-7).

#### Medical

##### *Diuretic Agents*

Often, a patient is offered a diuretic for lymphatic edema. Short-term diuretic use, during hospitalization for acute

edema reduction, accompanied by elevation and compression bandaging may be useful. Diuretics are usually not helpful in the chronic management of lymphedema because the effect is temporary and the diuresis leaves behind large protein molecules, creating a concentrated state in the interstitium (140).

##### *Antibiotic Therapy*

Antibiotic therapy is indicated in the management of infection associated with lymphedema (focal cellulitis). No controlled studies are available for a specific regimen, for lymphedema-related cellulitis; however, a program of 1 week per month prophylaxis of Penn VK 250 or 500 mg, four times daily, has been advocated by our group for those patients with several episodes of cellulitis per year (141). For those with a penicillin allergy, a first-generation cephalosporin, clindamycin, or erythromycin may be considered. Inflammatory destruction of remaining lymphatics secondary to repeated infections can worsen the clinical problem. Cellulitis requires prompt management with a 10-day course of oral antibiotics. If symptoms become systemic, intravenous antibiotics may become necessary. Recalcitrant infections may require a program of daily prophylaxis. Antibiotic prophylaxis should be considered for those patients with recurrent cellulitis of the affected limbs. All prophylactic programs must be accompanied by rigorous edema control measures. Patients who have a history of intertriginous

**FIGURE 45-7.** Left upper extremity lymphedema. **A:** Before treatment. **B:** After 2 weeks of specialized lymphatic massage and multilayered low-stretch compression bandaging.

fungal infection or who may be immunosuppressed should use prophylactic topical antifungal foot care.

### ***Benzopyrones***

Benzopyrones are thought to enhance fluid return by macrophage stimulation with increased proteolysis in the subcutaneous tissues. These agents have been reported to assist in edema reduction in both upper and lower extremities (142). However, a double blind cross-over study did not show any clinical benefit of benzopyrones compared to placebo (143). Reported side effects of benzopyrones include abnormal liver enzyme levels. Benzopyrones, although available elsewhere, are not widely utilized and are not approved by the U.S. Food and Drug Administration (143).

### ***Rehabilitation***

Comprehensive treatment regimens for lymphedema are referred to by various names, but most often called complex decongestive therapy. These treatment programs have become the standard of care. They include four common components: (a) skin care management and treatment of infection; (b) specialized massage techniques to promote the movement of lymph; (c) compression of the lymphedematous regions; and (d) elevation and exercises to reduce swelling and supplement the massage. After an active reduction phase (Phase I), an ongoing maintenance phase (Phase II) includes daily use of compression garments (and often continued nocturnal compression) to maintain reduction. General contraindications to aggressive lymphedema management include acute infection, cardiopulmonary edema, and ongoing malignant diseases. Conditions such as pregnancy, recent abdominal surgery, radiation fibrosis, DVT, and aortic aneurysm may preclude some portions of the treatment. Palliative lymphedema management is appropriate.

### ***Skin Care***

A vulnerability to infection exists wherever tissue fluids are poorly drained. Individuals with chronic lymphedema are susceptible to cellulitis from a variety of pathogens (144). Factors such as weak antigenic stimulation of regional lymphocytes and reduced extravascular macrophage function have been suggested as etiological contributors (145). Meticulous skin hygiene is imperative. The limbs should be washed regularly with soap and water and, while still moist, lubricated with an alcohol-free emollient cream.

### ***Specialized Massage***

Specialized lymphatic massage techniques in the form of manual lymphatic drainage cause collateral lymphatics of both superficial and deep networks to become dilated and carry more lymph and protein. Massage also facilitates the movement of tissue fluid and protein into lymphatic capillaries and along collecting lymphatics (146–149).

When deep lymphatic channels are blocked, there is considerable backflow of lymph into the network of superficial or dermal lymphatics. Where this occurs, massage is performed in a manner that promotes movement of fluid through superficial lymphatic vessels to patent lymph channels.

### ***Compression***

Compression of a lymphedematous region causes increased total tissue pressure, decreases the hydrostatic pressure gradient from the blood to the tissues, and increases the hydrostatic pressure gradient from the tissues to the initial lymphatics. The pressure gradient along the lymphatic trunks is also increased. Compression of the affected regions is necessary to maintain reductions in edema during and after the treatment. Lymphedematous regions may be compressed with bandages (elastic or low stretch) or graduated compression garments.

***Compression bandages.*** There are two basic types of compression bandages. Elastic high-stretch compression bandages have a high resting pressure (from elastic recoil) and low working pressure because they stretch in response to muscle contraction. Low-elastic or low-stretch compression bandages have a low resting pressure and a high working pressure, which increases the total tissue pressure when muscles contract. Lymphatic vessels are compressed between the muscles and the bandages enhancing transport. Proper compression bandaging includes greater pressure application at the distal end of the limb with gradually reduced pressure toward the proximal creating a pressure gradient. Bandages can be used with various types of padding beneath them to reshape the limb (Fig. 45-8).

**FIGURE 45-8.** Compression bandage. Multilayered low-stretch compression bandaging techniques create a pressure gradient without patient discomfort.

**Compression garments.** Once reduced stable limb volume is achieved, graduated compression garments are necessary to prevent fluid reaccumulation. Like compression bandages, compression garments enhance the pumping action of lymphatics and veins, and decrease the hydrostatic pressure gradient from the blood to the tissues. Compression garments are available in various levels of compression. For lymphedema, pressures of 30 to 40 mm Hg often suffice. Recalcitrant edema may require 40 to 50 mm Hg of support. Appropriate compression and fit of the garment along with skill of donning and doffing are critical to a successful management program. The style of the garment, fabric resistance, donning techniques, and wearing schedule should be optimized for each patient. Ill-fitting garments can cause pain and discomfort, leading to noncompliance and fluid reaccumulation. Vendor/industry options include prefabricated and custom garments in various sizes, fabric weaves, and color options.

### **Elevation**

Elevation of a lymphedematous limb can decrease the hydrostatic pressure gradient from the vasculature to the tissues and reduce the amount of fluid and protein moving out of the capillaries. Elevation can also increase the lymphatic flow by increasing the hydrostatic pressure gradient along lymphatic trunks. Patients are encouraged to elevate an involved limb periodically throughout the day. For some individuals, elevation of the affected extremity is the most effective reductive intervention.

### **Exercise**

Muscle contraction increases the total tissue pressure. This results in the active movement of fluid into and along initial lymphatics. The intrinsic pumping action of collecting lymphatics will also be enhanced by compression of these vessels between contracting muscles and surrounding fibrous tissues (150,151). Exercises are critical for fluid mobilization and should be performed while wearing either appropriate compression bandages or compression garments. The external compression augments the increases in tissue pressure and lymph flow. Historically, there has been concern that exercise may exacerbate lymphedema. A recent randomized controlled trial examined exercise and lymphedema in breast cancer survivors and found that a 6-month intervention of resistance exercise did not increase the risk for, or exacerbate symptoms of, lymphedema (152).

### **Vasopneumatic Compression Therapy**

Vasopneumatic compression pumps increase the total tissue pressure in edematous limbs and push tissue fluid back into blood capillaries. Because excess protein is not removed from the tissues (149,153), the concentration of tissue protein may increase, and lead to the reoccurrence of edema. Another limitation of compression pumps in the management of lymphedema is that they cannot apply pressure to areas of the trunk adjacent to draining lymph nodes (154). Pumps may also exacerbate genital edema or produce a collection of high

protein fluid proximal to the site of pumping, which may enhance inflammation and fibrosis. When using compression pumps for lymphedema management, pressures of 40 to 50 mm Hg are sufficient for fluid removal and to lessen the risk for tissue damage. It is the clinical observation of the authors that pneumatic compression is more helpful in the management of chronic venous insufficiency than in the management of chronic stage II or III lymphedema.

### **Surgery**

#### **Excisional Debulking**

Excisional debulking procedures have occasionally been recommended for patients with significant functional impairment due to excessive lymphedema (133). This may decrease the volume of the affected extremity when irreversible changes in skin and subcutaneous tissues have occurred.

#### **Reconstruction of Lymphatics**

Surgical reconstruction of obstructed lymph vessels and lymph nodes has been performed using lymphovenous anastomoses (155–157) or lympholymphatic anastomoses (lymphatic grafting) (158,159). Although clinical benefit has been reported by a few surgical groups, the long-term patency and function of such anastomoses is still uncertain. Currently, surgical treatment is reserved for those patients who have lymphangiectasia and primary chylous disorders (lymphedema, chylous effusions, and chylous fistula). Reconstruction of dilated lymph vessels in these patients is done with saphenous vein grafts (160). At present, lymphatic reconstructions are not considered a first-line treatment for chronic obstructive lymphedema.

## **CONCLUSION**

The patient with vascular disease poses a significant challenge to the rehabilitation professional. Arterial, venous, or lymphatic dysfunction may be the primary issue or a critical comorbidity in many patients who present to rehabilitation. These diseases may also be present in patients who present for presumably unrelated problems. A detailed vascular history, examination, and selected diagnostic tests should be inherent in the rehabilitation evaluation. When identified early by the rehabilitation professional, interventions including exercise, appropriate compression, modalities, positioning, protection, and proper footwear may ameliorate the need for more aggressive medical and surgical treatments in patients with vascular disease.

# Transplantation Medicine: A Rehabilitation Perspective

## INTRODUCTION

### History

The modern field of transplantation traces its origins to a successful renal auto-transplant in a dog performed in 1902. The development of vascular anastomosis, which underlies organ transplantation, was developed by Carrel (1,2) who is known as the father of transplantation although he did not pursue this as a career. For this development, he was awarded the Nobel Prize in Physiology. The recognition that allograft rejection is an immunologic process was discovered by Medawar (3). This classic series of studies foreshadowed the future by including descriptions of tolerance, a goal of transplantation (3–5). Progress in the field was fostered by the development of an understanding of the major histocompatibility complex (MHC), which in humans is referred to as the HLA, and the recognition that the HLA is the immunologic target of rejection (6). Developments in the understanding of cellular immunity and pharmacologic manipulation has allowed for the growth of the clinical field of transplantation medicine. Transplantation medicine is essentially only 30 years old, with the first successful trial in kidney transplantation in the 1970s and liver transplantation in 1980 by Starzl (7,8). These developments were supported by the development of immunosuppression agents such as cyclosporine and tacrolimus (FK-506) (7,9). In fact, small bowel transplantation has only been recently approved by the FDA as an acceptable treatment for short-gut syndrome. Nonetheless, the field has advanced to such an extent that transplant surgery is almost considered routine.

### The Transplantation Process

The reception of a transplant allograft in many ways represents a complete medical renaissance of an individual. The transplant patient is likely an extremely deconditioned, malnourished, cachectic individual with one, if not more, end-stage organ disease, whether it is cirrhosis, lung disease, and/or cardiac disease. Having withstood the often long and unavoidably bloody operation with its attendant risks (i.e., prolonged anesthesia, prolonged paralysis, single positioning), these patients are further deconditioned and commit themselves to a lifetime of immunosuppression with their associated side effects, for example, infection, rejection, steroid-related problems. Such

persons often have associated musculoskeletal and neuromotor impairments making rehabilitation an important part of their care.

Despite these seemingly insurmountable obstacles, the transplant patient is often able to return to be a highly functional, productive member of society. Transplant patients are running marathons, having babies, and returning to work as a state governor.

## ISSUES RELATED TO TRANSPLANTATION

Of importance to the rehabilitation specialist is a series of medical issues that impact the outcome in persons with transplant.

### Immunosuppression

Immunosuppression is a double-edged sword. While rescuing the transplant patient from the wave of rejection, these medications, in addition to exposing the patient to infection, have significant direct toxicities (Table 46-1). Most transplant centers that choose to treat long-term transplant survivors rely on the three-drug cocktail: cyclosporine, azathioprine, and prednisone. At many centers cyclosporine has been replaced with tacrolimus, and the use of prednisone has declined in most patients (1,2). Of interest, many patients at such centers require only monotherapy with tacrolimus and theories regarding the taper of immunosuppressive medications are being espoused (10). Other medications, including rapamycin (11) and mycophenolate mofetil, are also utilized and may be seen in transplant patients undergoing rehabilitation. Whatever the “primary cocktail” combination, the crucial component to immunosuppression resides in the calcineurin inhibitors, cyclosporine, and tacrolimus. Cyclosporine and tacrolimus work by inhibiting calcineurin, a phosphatase that acts on nuclear regulatory factor, the end effect of which is the inhibition of interleukin-2 (IL-2), a cytokine critical in T-cell activation and thus rejection (11).

### Cyclosporine

Cyclosporine, in combination with prednisone and azathioprine, in the early 1980s allowed for the high rate of graft acceptance seen today, and thus it is the mainstay of

**TABLE 46.1** Immunosuppressive Agents

Immunosuppressive	Mechanism	Role	Side Effects
Cyclosporine	Inhibits IL-2	Primary	Neurotoxicity Nephrotoxicity Electrolyte imbalance
Tacrolimus	Inhibits IL-2	Primary	Neurotoxicity Nephrotoxicity Electrolyte imbalance
Sirolimus	Inhibits IL-2	Primary/adjunct	Neutropenia Hyperlipidemia Concerns regarding bronchial anastomosis
Steroids	Cytokine inhibitor	Adjunct	Muscle wasting Poor wound healing Osteoporosis
Azathioprine	Purine synthesis inhibitor	Adjunct	Pancytopenia GI distress
Mycophenolic acid	Purine synthesis inhibitor	Adjunct	Pancytopenia Diarrhea

immunosuppression in many transplant centers. Cyclosporine is a unique agent that upon introduction nearly doubled the 1-year graft survival among those receiving kidney transplants (12). Working via the inhibition of calcineurin, cyclosporine acts to freeze antigen-activated lymphocytes at an early phase and potentially allows for a deescalation of the cycle of response (11,12). Both the drug and its metabolites are eliminated via the liver as a primary step and the kidney as a secondary clearance step (13).

### Concerns

Several medications interact with cyclosporine, especially those that act at the cytochrome P450 system. Anticonvulsant therapy leads to decreased levels, while several antibiotics and ketoconazole markedly increase levels of cyclosporine. Of importance is the fact that St. John's Wort interacts with cyclosporine to cause a decrease in cyclosporine blood levels. In several cases this has led to transplant rejection.

The main toxicity of cyclosporine is nephrotoxicity, occurring in approximately 18% of patients (14,15). Cyclosporine appears to inhibit renal function via multiple mechanisms, including vasoconstriction via endothelins and thromboxane stimulation, direct toxicity of vascular endothelium causing acute microvascular disease and inducing a chronic interstitial fibrosis (15,16). The two former mechanisms may be reversible, with reduction or cessation of cyclosporine, whereas the latter may progress to renal failure or, fortunately in many cases, stabilize. Loss of renal function remains significant with 9.5% requiring dialysis at 13 years post liver transplant (15,16). There is great variation in patient susceptibility to cyclosporine-based nephrotoxicity, although those with underlying renal impairment appear predisposed to renal failure

from cyclosporine. Urine output and creatinine remains the first line of nephrotoxicity detection. Elevation of creatinine should prompt a nephrology or transplantation consultation with a plan to lower cyclosporine if possible and if rejection is not a problem.

Neurotoxicity remains the other major side effect of cyclosporine, ranging from peripheral neuropathy, tremors, and dysesthesias, which are very common, to less commonly, seizures and full-blown encephalopathy (17–20). The fine motor tremor associated with cyclosporine therapy can often be diminished by adjustment of the medication and/or accommodation by the patient. Headaches secondary to cyclosporine therapy have been reported, and a demyelinating neuropathy can also occur (21).

Hypertension is associated with the use of cyclosporine therapy. It appears to be secondary to sodium and water retention, and as well as increased intracellular calcium (22,23). Other complications include electrolyte abnormalities such as mild hyperkalemia, which sometimes requires treatment (24,25). Lipid profile dysfunction is also noted with cyclosporine therapy. Hypomagnesemia is also common and may need oral replacement as it predisposes the transplant patient to seizures. Hypertrichosis and gingival hyperplasia are not medically severe, but can be cosmetically troublesome (26).

### Tacrolimus

Tacrolimus (FK-506) was introduced in the 1990s and is considered more potent than cyclosporine. This agent has been reported to be as much as 100 times more potent than cyclosporine (27). Tacrolimus is a metabolite of the fungus *Streptomyces tsukubaensis*. It is a macrolide, highly plasma bound, and processed in a variable fashion via the liver in the cytochrome

P450 system (28,29). Tacrolimus immunosuppressive action is similar to that of cyclosporine, working via the calcineurin system. Tacrolimus has allowed for steroid-free therapy, and has permitted small bowel transplantation to be more acceptable (30). Several large trials have examined the efficacy of tacrolimus in preventing rejection after liver transplantation (31). The incidence of acute and chronic rejection appeared to be lowered by the use of tacrolimus. There also appeared to be more retransplantations required in the non-tacrolimus-treated group (32,33). In a study of over 1,000 liver transplant patients by Jain et al., they concluded that chronic rejection occurred rarely among patients maintained long term on tacrolimus-based immunosuppressive therapy (33). In addition, the Multicenter Tacrolimus Rescue Trial has shown that among transplant patients receiving cyclosporine who are experiencing chronic rejection, many can be salvaged by transfer to tacrolimus (34). An additional potential benefit of tacrolimus is that it has been shown to demonstrate a reduction in serum cholesterol when compared to cyclosporine (35,36).

### Concerns

Tacrolimus, being also a calcineurin inhibitor, has a toxic profile remarkably similar to that of cyclosporine, although neurotoxicity is more prevalent (37,38). Susceptibility to neurotoxicity may have a genetic relationship. In a study by Yamauchi (39), the genotype of six patients who had experienced neurotoxicity after liver transplantation was examined. The authors found a relationship between neurotoxicity associated with polymorphism in the ABCB1 gene (39). Resting tremor is the most common neurologic adverse reaction although more serious effects such as peripheral neuropathy and encephalopathy have been reported. Debate exists as to how often this profile of side effects occurs among those taking tacrolimus when compared to the population utilizing cyclosporine for immunosuppression (37). Shimono (40) utilized diffusion weighted MRI to evaluate those that developed neurotoxicity following organ transplantation. He noted that 35.7% had white matter abnormalities, 7.1% had putaminal hemorrhage, and 57.1% had normal findings on MRI (40). Bartynski (41) evaluated 22 patients with a neurotoxic reaction. He also noted the significance of white matter lesions in this population. Patients often have tremors initially, although personal observation suggests that there may be an acclimation to the drug. For persistent tremor that affects activities of daily living, low-dose clonazepam may be helpful.

Drug interactions are common, especially when using itraconazole or ketoconazole since hepatic metabolism is inhibited, risking toxicity. Because of profound hypomagnesemia, frequent monitoring of magnesium levels should be done and often both oral and intravenous (IV) supplementation is required.

### Sirolimus

Sirolimus (Rapamycin) is an immunosuppressive that inhibits the cell cycle and the activation of IL-2 (42,43). This agent is produced by *Streptomyces hygroscopicus*. Sirolimus is still

finding its place in immunosuppression as either a primary drug or adjunct with tacrolimus or cyclosporine. Its mechanism of action is different from either cyclosporine or tacrolimus in that it does not inhibit calcineurin (44). Sirolimus appears to prevent the translation of mRNA impacting cell cycle regulation (45–47). Sirolimus, being nonnephrotoxic, is a viable alternative in patients who develop renal insufficiency caused by calcineurin inhibitors (42,48–50). In a retrospective review, patients who were more than 3 years posttransplantation were selected to evaluate the role of sirolimus. Patients who had proteinuria, those administered any other nephrotoxic agents, and those with a creatinine clearance less than 20 mL/min were excluded. Renal insufficiency was defined as mild, moderate, or severe. In the 16 patients studied, there was significant improvement in serum blood urea nitrogen and serum creatinine levels 6 months after switching to sirolimus therapy. No patient developed cellular rejection or other graft-related complications (51). Among liver transplant recipients with chronic renal insufficiency, conversion to sirolimus-based immunosuppression may allow complete withdrawal of other agents, leading to some improvement in renal function. Another recent study evaluated the safety and efficacy of sirolimus plus steroids as a maintenance regimen with or without small-dose cyclosporine adjunctive therapy in renal transplantation (52). A total of 133 recipients of kidney allograft transplantations recruited in the United Kingdom and Ireland were enrolled into the study. Patient and graft survival were 97.7% and 95.5%, respectively, whereas the biopsy proven acute rejection rate in the first 6 months was 19.5%; incidents of acute rejection rates comprised 22 episodes (16.5%) during the first 3 months of the study and four episodes (3%) after randomization. These data demonstrate that withdrawal of cyclosporine from a small-dose sirolimus maintenance regimen is safe and is associated with an improvement in renal function (52). The study also suggests that the addition of small-dose cyclosporine to a sirolimus maintenance regimen does not increase the immunosuppressive efficacy. A recent study of 26 subjects receiving liver transplantation who experience nephrotoxicity owing to calcineurin inhibitors, suggests successful transfer to sirolimus monotherapy is possible and results in improved renal function (53).

### Concerns

Sirolimus causes neutropenia and hyperlipidemia and may predispose patients to more infection. Its antiproliferative properties can also delay healing (54). It is also noted to cause thrombocytopenia, and has also been suggested to have prothrombotic activity. Sirolimus increases the levels of cyclosporine, when used in combination. Even though sirolimus is not primarily nephrotoxic, dual treatment groups have noted an increased incidence of nephrotoxicity (55). Combination sirolimus-tacrolimus may cause nephrotoxicity in some patients by mechanisms that are presently unexplained. Sirolimus appears to prolong delayed graft function (DGF), therefore, it may not be the optimal immunosuppressive choice in the DGF setting (56). A report of delayed wound healing in a person treated

with sirolimus who received a liver transplant has been noted, and late wound dehiscence can occur as well (57).

### Corticosteroids

Corticosteroids have been used in transplantation medicine since the early days of solid organ transplantation. These agents impact the functional capacity and the concentration of active leukocytes (58). This tends to occur via the regulation of cytokine gene transcription. These agents have value as adjuvant therapy, at times of stress, and in the treatment of mild-moderate acute rejection. Several attempts have been made at discontinuing steroid therapy. The most successful of these have been programs with tacrolimus-based paradigms (59,60).

Corticosteroids have long been a cornerstone of orthotopic liver transplant immunosuppression. Newer, more potent agents have successfully allowed for more rapid tapering and discontinuation of corticosteroids in liver transplant recipients. Washburn (60) hypothesized that corticosteroids can be safely avoided after the first postoperative day using these newer agents. Thirty adult orthotopic liver transplant recipients were prospectively enrolled in a randomized open-label protocol. The incidence of biopsy-proven acute rejection requiring steroid therapy was 6.7% in both the steroid and the “no steroid” groups. Serum cholesterol levels were significantly lower in the “no steroids group” at 6 months after transplantation. Serum triglycerides were also lower, but the difference was not significant. Boots (61) evaluated the role of steroids in renal transplantation, by comparing tapering in 3 to 6 months, with stopping steroids 1 week posttransplantation. Results were noted to be comparable in patients and graft survival, with a similar incidence of acute rejections. The incidence of new-onset diabetes may be reduced among those receiving early taper from steroids (61). The immunosuppressive benefit of adding enteral prednisone to tacrolimus seems to be limited. In a prospective, randomized, double blind, placebo controlled, multicenter study of early steroid withdrawal versus chronic steroid therapy for those with renal transplantation, Woodle et al. (62) noted that early steroid withdrawal is associated with an increase in biopsy-associated rejection (usually mild) yet results in similar allograft survival and function.

The side effects of long-term steroid use are well described and are significant in transplant patients. These include poor wound healing, glucose intolerance, osteoporosis, anasarca, muscle wasting and myopathy, and emotional lability. Lipid abnormalities have also been described. Genotypic testing noted that the presence of an Apolipoprotein E4 allele worsened high-density lipoproteins (HDL), triglycerides, and cholesterol (63). Thus, Apolipoprotein E4 has a larger impact than Apolipoprotein E2 on fasting-lipid profile in transplant candidates. There have been occasional reports of acute respiratory and skeletal muscle weakness in intensive care unit patients treated with massive doses of corticosteroids for rejection prophylaxis or treatment. Compared to the pretreatment condition, approximately 45% of patients showed acute generalized muscle weakness that recovered after approximately 2 months

(64). If given a “risk-free” choice, the majority of recipients prefer withdrawal of steroids (65).

### Alternative Agents

Azathioprine and mycophenolic acid are adjunctive immunosuppressive agents that inhibit purine synthesis; thereby generally inhibiting immune cells, particularly lymphocytes. These agents have been noted to block de novo purine synthesis by blocking key enzymes. This process is required by T and B lymphocytes for proliferation (66). The role of mycophenolic acid as adjunct therapy in preventing rejection has been established among those with renal and heart transplantation (67). Mycophenolate combined with cyclosporine and prednisone significantly lowers acute rejection frequency in the early post-renal transplantation phase (67). A comparative retrospective analysis of the 5-year results with mycophenolate was performed by Offerman (69). Both the total population and subgroups showed a nonsignificant trend toward better graft survival with mycophenolate, evident at 2 years and persisting for 5 years. Extrapolation indicates that combination therapy with mycophenolate versus azathioprine, results in approximately 10% more patients being alive at 10 years with a functional graft. These agents are also employed in the treatment of acute rejection in such populations (68). Side effects include diarrhea that can mimic *Clostridium difficile* infection, neutropenia, and pancytopenia. Thymoglobulin was effective as induction therapy in high-risk pancreatic transplant recipients, and resulted in initial reversal of rejection in 74% of patients. Dose adjustments were required in over half the cases and were usually due to leukopenia. Infections occurring subsequent to thymoglobulin were not uncommon and reflected the immunosuppressive burden of the patient population (70).

### Monoclonal Antibody Agents

A major thrust of transplantation research is to find more effective and less broadly toxic immunosuppressive agents. One potential way is the use of monoclonal antibodies directed to IL-2 receptors. Several monoclonal antibodies have been introduced that target the IL-2 receptor. Daclizumab and Basiliximab focus on the  $\alpha$ -2 chains of the IL-2 receptor (71,72). Pediatric patients appear to be among those that benefit the most from anti-IL-2 receptor therapy (73). Immunoprophylaxis with daclizumab has been shown to be effective in the prevention of acute rejection in kidney transplant patients. Niemeyer initiated a pilot study in 28 liver transplant patients. Daclizumab was administered intravenously. At 4 years post-transplant, no lymphoproliferative disease was observed (74). Immunoprophylaxis with a two-dose daclizumab regimen appears safe, effective and well tolerated, and does not lead to increased opportunistic infections. Such agents are utilized in combination with the agents previously described (74–77). A two-dose regimen appears to be as effective as the five-dose regimen in preventing acute rejection and is associated with the lowest acute rejection rates and the highest rate of event-free survival (no rejection or graft loss). However, the benefits

**FIGURE 46-1.** Complications of transplantation.

of daclizumab compared with no antibody induction await larger sample size accrual (78).

### Gene Therapy

One major complication facing organ transplant recipients is the requirement for life-long systemic immunosuppression to prevent rejection, which is associated with an increased incidence of malignancy and susceptibility to opportunistic infections. Presently, exciting investigations into the role of gene therapy for immunosuppression are underway. A further understanding of genetic polymorphisms may also assist in defining those who are at risk for complications such as graft versus host disease (79). Gene therapy has the potential to eliminate problems associated with immunosuppression by allowing the production of immunomodulatory proteins in the donor grafts, resulting in local rather than systemic immunosuppression (80,81). The use of gene therapy may also make xenografts more practical. Alternatively, gene therapy approaches could eliminate the requirement for general immunosuppression by allowing the induction of donor-specific tolerance. Gene therapy interventions may also be able to prevent graft damage owing to non-immune-mediated graft loss or injury and prevent chronic rejection (80,82; Fig. 46-1).

### INFECTION

Immunosuppression places these patients at extreme risk for opportunistic infections, which has probably remained the most significant cause of morbidity and mortality in the transplant recipient. Since the immunosuppressive regimen includes medications that suppress both T and B cell action, these patients are vulnerable to many types of infections: bacterial, viral, fungal, tuberculosis, and pneumocystis. Several of these

infectious agents are not typically seen in immunocompetent individuals. Despite the fact that aggressive pretransplantation infectious evaluation is part of every protocol, infections are common. Moreover, immunosuppressives, especially prednisone, may mask infectious etiologies making the diagnosis of infection difficult in transplant patients (83). Fever and leukocytosis are still the most common signs of infection, although their absence does not rule it out. Systemic infection may present with a low-grade temperature or no fever at all. It is not uncommon for a transplant patient to have two simultaneous opportunistic infections. Again because of the immunosuppression, once a patient begins to show signs of infection, the course to fulminate sepsis and potentially death can be brief and dramatic (84–86). Vigilance and a high index of suspicion is the rule in detecting infections in transplant patients. During the past decade, ever-increasing numbers of patients have undergone renal, pancreatic, small bowel, hepatic, cardiac, or lung transplantation. Significant improvements in patient and allograft survival have been observed in all categories. Unfortunately, despite such improved results, the risks of infection related to immunosuppression continue to be substantial. Dunn performed a review of transplant-related nosocomial infections. These authors noted that suppression of host defenses by exogenous immunosuppressive agents renders patients susceptible to invasion by either resident or environmental bacterial, fungal, viral, and protozoal microbes or parasites (87). Invasion of organisms that typically produce mild infection in nonimmunosuppressed individuals can produce severe, lethal disease in those receiving immunosuppressive agents. Thus in an ideal world, immunosuppression could be decreased or eliminated in such patients.

Posttransplantation infections can be divided into three main etiological categories based on time after surgery: During the first 3 to 4 weeks infections are related to technical and mechanical problems (i.e., line infections, abscess, cholangitis from biliary stenosis, bowel obstruction, and wound infections). In a second phase, the first through sixth months posttransplant, cytomegalovirus (CMV) accounts for two thirds of infections, and beyond 6 months, infections are similar to that seen in a general population (88,89). The typical transplant patient receiving acute inpatient rehabilitation is in the first category, although now with long-term transplant survivors, physiatrists are also treating posttransplant patients with other medical problems, such as hip replacement in a patient with an allograft.

Along with factors related to immunosuppression, those receiving transplant may have prolonged hospitalization and thus secondary infection. Common pathogens include *Aspergillus*, *Staphylococcus*, *Clostridium difficile*, *Pseudomonas aeruginosa*, and *Legionella*. Viral infections are also quite possible and include: CMV, Epstein Barr virus, Herpes Simplex, Varicella Zoster, Hepatitis B and C (90).

Pulmonary infections are the most common cause of morbidity in the lung transplant population. Prompt recognition and treatment is necessary to prevent poor outcomes. An understanding of the temporal relationship between

immunosuppression and the risk for developing infection can assist the clinician with appropriate treatment. Bacterial pneumonia is common within the first 4 months after transplantation whereas CMV infection becomes more prevalent after the discontinuation of prophylaxis in at-risk patients (91,92). Fungal infections, especially aspergillosis, can be fatal if not treated early and the risk for infection is present throughout the transplant period. Community-acquired viral infections present with upper respiratory symptoms and wheezing that may lead to a persistent decline in lung function. Suspicion of a pulmonary infection in these immunosuppressed individuals should lead to an urgent diagnostic bronchoscopy and empiric antimicrobial therapy (90).

CMV is the most common infection in transplant patients and deserves significant attention. CMV is usually found latent in either recipient or donor and becomes active in a milieu of immune inhibition (91,92). The most virulent CMV infection is seen when a CMV naïve recipient succumbs to CMV carried within the donor allograft. CMV can be widely disseminated and infection can occur anywhere in the body. Fever, leukopenia, and generalized malaise are the most common symptom; although, pneumonitis, hepatitis, cholecystitis, and colitis with occasional GI bleed are not uncommon (92). Posttransplant CMV infection has been associated with posttransplant arteriopathy and can signify invasive infection (93). In many transplant centers, a fever work-up includes CMV culture and antigen detection. In our center, all transplant patients receive prophylaxis with acyclovir (200 mg PO bid), and active treatment is initially with IV ganciclovir (5 mg/kg for 3 to 4 weeks followed by maintenance dose orally for a specified period of time, usually months) (94). Treatment is continued until the patient has three consecutive CMV antigen negative tests. CMV antigen detection is done weekly at many institutions for all patients within the first month of their operation.

Fungal infections are also more common in the immunosuppressed transplant patients than the general population. The clinician has to be vigilant because fungal infections can be devastating. Feltis (95) has noted mycotic aneurysms after transplantation. Fungal infections are associated with high morbidity and mortality, and make up a significant proportion of infectious complications. Unfortunately, the diagnosis is usually made late, and symptoms may be mild and nonspecific, even with dissemination. Mortality associated with disseminated fungal infections is high, while those associated with more local fungal infections is low (96). Although the risk factors for invasive fungal infections in liver transplant patients are well identified, early diagnosis is challenging, and commonly used diagnostic methods lack sensitivity and specificity (96). The incidence of fungal infections following liver transplantation appears to be falling. Future developments should focus on enhancing earlier diagnosis, implementing more effective and less toxic antifungal therapy recipients (97,98). Early fungal infections are related to surgical complications, while the period of 1 to 6 months after transplant reflects opportunistic, relapsed, or residual infections; fungal infections greater than 6 months after transplant and thereafter are usually associated

with treatments for chronic rejection or bronchial airway mechanical abnormalities (99). The majority of fungal infections in lung transplant recipients involve *Aspergillus* species, followed by *Candida*, *Pneumocystis*, *Cryptococcus*, geographically restricted agents, and newly emerging fungal pathogens. Virulent infections such as *Aspergillus* or *Mucormycosis* are usually fatal. *Aspergillus* can be widely disseminated and may not grow in culture despite systemic infection (100).

Of note, persons receiving lung transplants for cystic fibrosis appear to be at particular risk for *Aspergillus* infection (100). The isolation of *Aspergillus fumigatus* from respiratory tract specimens in heart transplant recipients appears to be highly predictive of invasive aspergillosis (101). The presence of *Aspergillus* “fungus balls” lesions in the brain usually means death, and lung involvement requires resection for any chance of survival. *Mucormycosis* spreads by the nasal sinuses into the brain where their infection portends death; cure, if caught early enough, requires aggressive debridement and resection of facial tissues.

## REJECTION

Rejection exists as a continuum of responses that are important to understand. Transplant rejection has been classified as hyperacute, acute, subacute, and chronic. Hyperacute rejection occurs when the recipient has antibodies to antigens present on the transplanted organs. This elicits an aggressive immune response resulting in organ failure. This response type has generally been limited by extensive routine cross matching. Acute rejection is a relatively intense inflammatory response to the new organ. The inflammation that occurs has been described as being similar to that seen in a hypersensitivity type of reaction (102). The result of this reaction is the deposition of a large number of inflammatory cells within the graft. The clinical syndrome manifests itself as rubor, edema, fever, and pain. The transplanted organ's function-related laboratories may also become acutely impaired. Despite potent immunosuppression, more chronic forms of rejection are still a common event usually within the first 3 months after transplantation. Symptoms such as fever and leukocytosis are sometimes present although rejection often occurs in the absence of these symptoms. Usually subacute and chronic rejection is heralded by a rise in an allograft laboratory value, such as increased creatinine in persons with renal transplant, increase in bilirubin or liver function enzymes in persons with liver transplantation, and elevation in amylase and lipase among those with pancreas transplants. Tissue biopsy, usually obtained percutaneously, with histologic examination remains the gold standard for the diagnosis of rejection. The incidence of chronic rejection varies by type of solid organ transplantation. The incidence of chronic rejection has been reported as high as 50% in the lung transplantation population and as low as 5% among those receiving liver transplantation (103,104).

Chronic allograft nephropathy (CAN) is, besides death of the recipient, the most common cause of renal transplant loss.

**TABLE 46.2** Rejection Symptoms

Type	Symptom	Treatment
Hyperacute	<ul style="list-style-type: none"> <li>Occurs in OR during initial transplantation surgery.</li> <li>Secondary to preformed antibodies.</li> <li>Graft is lost.</li> </ul>	<ul style="list-style-type: none"> <li>Graft replacement/retransplantation</li> </ul>
Acute chronic	<ul style="list-style-type: none"> <li>T-cell-mediated antigraft inflammatory infiltrate</li> <li>↑ LFT in liver transplants.</li> <li>↑ Glucose in pancreas transplants.</li> <li>↑ Blood urea nitrogen (BUN) with creatinine in kidney transplants.</li> <li>↑ Heart/lung biopsy may reveal ↑ inflammation.</li> <li>There may be ↑ inflammation.</li> <li>↑ Shortness of breath.</li> <li>↑ Edema</li> </ul>	<ul style="list-style-type: none"> <li>Solumedrol; if steroid resistant, thymoglobulin or OKT3</li> <li>Organ replacement is the treatment of choice.</li> <li>Possibly ↑ FK-506 or give steroid bolus.</li> </ul>

It is characterized by loss of function and replacement of tissue by fibrotic material (103). The pathogenesis is not clear, but seems to be multifactorial and involves events both early and late after transplantation.

A new and exciting concept is that of tolerogenic immunosuppression. Under this concept, individuals develop a partial tolerance to the transplanted organ and thus require less immunosuppression without associated rejection. This concept focuses on the principle of recipient pretreatment and minimum use of posttransplant immunosuppression. Starzl et al. (105) evaluated 82 persons awaiting various solid organ transplants. Posttransplant patients were maintained on sirolimus and subsequently tapered in dose after 4 months of therapy. Immunosuppression-related morbidity was virtually eliminated and transplant graft survival at 1 year was 89% (Table 46-2).

Once the diagnosis of acute rejection is confirmed, treatment is initially with high dose steroids (Solumedrol 1 gm) and a steroid taper that will successfully treat 80% to 85% of allograft rejection. Steroid-resistant rejection can be treated with antibodies, OKT3, or thymoglobulin, which will resolve 95% of all rejections. Resolution is characterized by the normalizing of laboratory values, so that follow-up biopsy is usually not necessary. Solumedrol administration and a steroid taper can be given in the rehabilitation unit without impacting the patient's level of activity. Antibody treatment will require closer monitoring and is best done upon transfer to a specialized transplant service.

## MALIGNANCY

Immunosuppressive therapy for organ transplant recipients is complicated by high rates of malignant diseases, one of these being Kaposi sarcoma (KS) (106). A review of 1075 patients who underwent kidney transplantation between 1985 and 2002 noted that a total of 52 malignant diseases were observed

in 50 patients (4.7%), during the posttransplantation period (107). KS was identified in 16 of these 50 individuals. One recipient had concomitant lymphoma and KS. The lesions of seven patients were limited to the skin, five cases involved the skin and gastrointestinal tract, and four patients had disseminated disease (108). At the time of writing, nine individuals were still alive: four had normal renal function and five had lost their grafts as a result of chronic rejection. The combination of immunosuppressive drug withdrawal and chemotherapy appears to be very effective in patients with limited disease, but the results in cases of generalized disease have been poor (108). It is believed that the calcineurin inhibitors have an independent cancer promoting effect and only rapamycin has shown simultaneous immunosuppression and antitumor effect (109).

Posttransplant lymphoproliferative disease (PTLD) is a lymphoid neoplasm that has been associated with immunosuppressive therapy (110). The exact mechanism of this malignancy in the posttransplant population is not well understood, however, as predicted and subsequently verified in 1968, an increased incidence of certain de novo malignancies has been observed, particularly with regard to lymphoid neoplasms (111). Jain et al. (112) performed a retrospective review of 4,000 consecutive patients who underwent liver transplantation. The 1-year patient survival for liver transplant patients with PTLD was 85%. The actuarial 20-year survival was estimated at 45%. The overall median time to PTLD presentation was 10 months, and children had an incidence of PTLD that was threefold higher than adults (112). Patient survival was better in children, in patients transplanted in the era of tacrolimus immunosuppression, in patients with polymorphic PTLD, and in those with limited disease.

While the overall incidence of PTLD in pediatric liver transplant recipients has been reported to be 4% to 11%, the long-term risk of PTLD associated with primary tacrolimus therapy was determined by Cacciarelli et al. (113). These authors evaluated 131 pediatric recipients who underwent

liver transplantation and received primary tacrolimus therapy. Pre-transplant Epstein-Barr virus (EBV) serologies were negative in 82%, positive in 12% of the patients (113). The cumulative long-term risk of PTLT was found to increase over time. Mortality from PTLT was 12% and a suggestion exists regarding a causal relationship with EBV status. EBV surveillance should occur in early posttransplantation (113).

Recurrent and de novo malignancies are the second leading causes of late death in liver transplant recipients, following age-related cardiovascular complications (106). The greatest incidence of de novo malignancies is seen in cancers associated with chronic viral infections, such as EBV-associated PTLT and skin cancers, including squamous cell carcinoma and KS (110).

## SOLID ORGAN TRANSPLANTATION

### Liver Transplantation

The achievement of liver transplantation by Thomas E. Starzl is one of the most remarkable technical surgical accomplishments and remains one of the most complicated operations in surgery. As such, it is metabolically demanding on the patient. Operating in patients with portal hypertension and all of its stigmata, including friable varices and hypocoagulability can be challenging. Because of the multiple vascular anastomoses (IVC, portal vein, hepatic artery), and the extensive dissection in the right upper quadrant, bleeding postoperatively can also be significant. Usually 2 to 4 Jackson-Pratt drains are placed to drain the suprahepatic space where bleeding from the IVC anastomosis can occur, to drain the subhepatic space where the infrahepatic IVC, portal, and hepatic artery anastomosis may bleed, and near the hilum to detect bile leaks from the biliary anastomosis (114). These drains are usually removed by 1 week, although some may stay longer if they are draining copious amounts of ascites postoperatively. T-tube stenting across the biliary anastomosis is also commonly done, and these are removed months after liver transplantation, but can be capped if the bilirubin has normalized to allow internal drainage of bile. Most patients in rehabilitation units will have T-tubes, but not drains.

Vital signs and two to three times weekly laboratory values for complete blood count (CBC), liver function tests (LFTs), and immunosuppressive agent levels are sufficient for routine screening. Fever, leukocytosis, or sudden leukopenia should prompt a fever work-up including CMV titer and culture (115). An elevated total bilirubin is the most sensitive indicator of rejection; however, increases of AST, ALT, and/or gGTP may signify rejection as well as infection (hepatitis), and vascular or biliary complications. Hepatic artery aneurysm and thrombosis are significant complications after transplantation (116,117). Persistence of ascites or the sudden development of ascites in a recent liver transplant patient should prompt an examination of the vasculature of the liver allografts to rule out outflow obstruction or portal vein thrombosis (117). An abdominal ultrasound to assess the hepatic vessels is the

first step toward diagnosis. A T-tube cholangiogram should be obtained and if these studies are unrevealing, a biopsy to rule out rejection should be performed (118,119). These studies are usually completed with the patient returned to the primary care of the transplant team. It is obvious that close coordination between the physiatrist and transplant surgeon is critical to the optimal care of the patient, especially in these situations.

### Renal Transplantation

Unlike liver transplantation, renal transplants are relatively routine and the operation is straightforward. The kidney allograft is placed in the iliac fossa in the retroperitoneal position. The renal artery and vein are anastomosed to the iliac artery and vein, respectively, and the ureter is implanted onto the bladder medially. Lasting only 2 to 4 hours in duration, renal transplantation is not associated with much blood loss. Drains are not usually placed, but in rare situations in which the renal bed is drained, they are removed within 3 to 5 days. Foley catheters are kept for 5 to 7 days to decompress the bladder and protect the ureteral anastomosis.

Graft function is assessed by urine output and creatinine levels. Urine output less than 50 cc/h should prompt an investigation into the cause, keeping in mind the most common cause being hypovolemia. A fluid challenge should be the first step. The goal for urine output in a patient with a renal transplant is approximately 2 L/d. A rise in creatinine signifies renal derangement that could be associated with hydronephrosis, urinary tract infection (UTI), rejection, or immunosuppressive toxicity. Doppler ultrasound is the first test to obtain to rule out an anatomic abnormality such as hydronephrosis that may be due to stricture of the ureterovesicular anastomosis. It can also rule out a perinephric collection that compresses the allograft and prevents perfusion (120,121). Finally, the ultrasound can examine the vessels to assess patency and flow, and to rule out thrombosis or stenosis (122,123). A simple urinalysis and culture will help to rule out a UTI. A history of trough levels of immunosuppression may suggest drug toxicity, although tacrolimus or cyclosporin nephropathy can occur with normal levels. A renal biopsy will rule out rejection or drug toxicity (120). First-line therapy for rejection is steroids and antibodies (OKT3, thymoglobulin), if the creatinine does not fall to baseline.

Finally, most renal transplant patients are diabetics or have hypertension, and are vulnerable to cardiac disease (124). Almost all renal patients undergo a cardiac work-up, including a dobutamine echo, but this work-up is not foolproof. Incidences of myocardial ischemia occur with intraoperative graft reperfusion when blood pressure drops, and at postoperative days 3 to 4 when the patient is mobilizing fluid from the interstitium back to the intravascular space (125). These problems are handled by standard medical guidelines.

### Pancreas Transplantation

Pancreas transplantation is usually offered to type I diabetics with severe diabetic end-organ damage. End-stage renal failure,

severe gastroparesis, neuropathy, retinopathy, and especially hypoglycemic unawareness, are indications for pancreas transplantation. Patients are offered simultaneous kidney and pancreas transplants, pancreas transplant after having a kidney allograft, or pancreas transplant alone (126). The pancreas allograft is typically placed in the iliac fossa, more commonly on the right because of anatomical advantage and the exocrine drainage can be to the small bowel or to the bladder. Recently, there has been a general trend to more enteric drainage due to the complications associated with bladder drainage, including pain, UTI, and bicarbonate loss (127).

There are very strict criteria for the selection of a donor pancreas and recipient, simply because the pancreas is a fragile organ prone to many potential morbidities. For instance, donor or recipient age above 45 is associated with increased morbidity and mortality (127). Isolated pancreas graft survival, which has the worst outcome amongst liver, kidney and pancreas transplants, is only 75% at 1 year and 66% at 5 years, although there has been steady improvement in the last 10 years. Overall morbidity (fistulas, leaks, bleeds, pancreatitis, infection, necrosis, abscess) can be up to 80% (125,128,129). Unlike kidney or liver, there are only a small number of transplant programs in the United States that perform more than 30 pancreas transplants/year.

The postoperative management of a pancreas transplant patient can be very challenging for the surgeon and physician alike. The usual course for the pancreas recipient can be “stormy” in the first month, during which time daily or every other day laboratory tests including electrolytes, CBC, amylase, and lipase should be taken. Fasting blood glucoses should be obtained four times per day, and c-peptide levels weekly to assess the pancreas function. These patients can take a regular diet, and fasting glucoses should be less than 150, and in many cases less than 100. Recent surgery as well as the heterotopic placement of a pancreas allograft makes these patients prone to ileus, or diarrhea, making nutrition potentially problematic in the early postoperative period.

Venous thrombosis, which occurs in 10% to 15% of all pancreas transplants, usually occurs during the first 2 weeks postoperation, but can occur anytime (124). A sudden and persistent rise in the blood glucose (>200) should prompt an immediate pancreas ultrasound and nuclear flow scan to rule out thrombosis, and immediate notification of the transplant service as this situation can be potentially dangerous.

Enteric leak at the anastomosis can also occur in 10% of all pancreatic transplants, and can be potentially fatal. Leaks usually occur within the first month of transplant. Fever, abdominal pain, signs of sepsis, and leukocytosis are the usual manifestations of this problem. A computed tomography (CT) scan without IV contrast is usually obtained to rule out leak, and notification of the transplant service should be done as this is a surgical emergency. The presence of steroids and immunosuppression, which can mask peritonitis, makes this diagnosis tricky.

Pancreatitis and its complications such as fistulas, pseudocyst, necrosis, can often occur anytime posttransplantation.

All of these conditions can result in the elevation of amylase and lipase levels, which are also indicators of rejection. Again, ultrasound is the first test obtained to evaluate for fluid collections, and to examine vascular flow in the pancreas. Once a collection is ruled out, a pancreas biopsy should be performed, if technically possible, to delineate pancreatitis from graft rejection. Mild pancreatitis can be observed or treated with sandostatin. More severe pancreatitis, in which there is tenderness over the graft, is best treated by making the patient NPO, and administering total peripheral nutrition (TPN) and sandostatin.

Percutaneous biopsy is the only way to conclusively diagnose pancreas rejection, but this can be technically difficult to perform (130–132). Those patients with simultaneous pancreas and kidney transplants from the same donor have the advantage of the kidney as a sentinel organ for rejection. Kidneys are less technically demanding to biopsy, and the creatinine levels serves as another marker of rejection. An increase in amylase and lipase is the best marker of allograft rejection, although the differential diagnosis of hyperlipasemia is not small. Moreover, in small number of cases, there is pancreas rejection without an increase in lipase (133). The pancreas is not as resilient as other types of allografts, so rejection should be treated aggressively. Mild rejection is usually treated with steroid therapy. Antibody treatment is used for steroid-resistant rejection or for moderate to severe pancreas rejection, depending on surgeon judgment.

### Small Bowel Transplantation

Small bowel transplantation is reserved for patients with irreversible intestinal failure who no longer can be maintained on total parenteral nutrition. Small bowel transplant can be offered as an isolated transplant, in combination with liver allograft, or as part of a multiviscera transplant, which includes liver, pancreas, stomach, and small bowel. Short-gut syndrome (midgut volvulus, necrotizing enterocolitis), intestinal dysmotility, or enterocyte failure (radiation enteritis, autoimmune enteropathy) are some indications for small bowel transplants (134). Chronic TPN can cause liver disease secondary to cholestasis, adding the need for a liver transplant with the small bowel. Finally, extensive thrombosis of visceral vessels may necessitate a multiviscera transplantation.

The small bowel transplant patient will likely be malnourished, cachetic, and deconditioned. The rehabilitation team can expect intestinal transplant patients to have an ostomy stoma, gastostomy tube, and jejunostomy tube. The gastostomy tube is usually clamped unless the patient experiences vomiting or bloating at which time the gastostomy tube can be unclamped for decompression. During the postoperative period, enteral nutrition is required and oral intake is often as tolerated. Occasionally, intestinal absorption remains suboptimal and TPN is still required. Patients require frequent biopsies via colonoscopy as well as careful clinical and tissue observation for rejection (135). Persistent diarrhea because of dumping syndrome is extremely common and can be controlled with Immodium and tincture of opium. Nutrition consultation is usually necessary and helpful. The psychiatric manifestation

and narcotic dependency from chronic abdominal pain, and the use of TPN can hamper optimal rehabilitation (136). For this reason, intestinal transplant patients especially require neuropsychological evaluation and counseling. An appropriate goal during the rehabilitation phase is transition from IV pain medication to orally dosed medication as long as absorption is adequate.

### Lung Transplantation

Hardy completed the first human lung transplant in 1963; during the next decade several attempts at human lung transplantation were completed, however, survival was brief (137–139). In the early 1980s several reports of long-term successful lung transplants surfaced. The first was a series of combined heart-lung transplants. These had the advantage of insuring adequate bronchial perfusion. Evolution of technique has allowed for single and double lung transplantation while avoiding bronchial airway ischemia. The United States waiting list for lung transplantation now exceeds 3,000.

Those persons with pulmonary fibrosis, chronic obstructive pulmonary disease (COPD), pulmonary hypertension, and chronic bronchitis often present as candidates for transplantation while in their 60s and 70s. Many have comorbidities and should receive a careful screening for malignancies. Among younger patients, those with cystic fibrosis often require transplantation (140). Such patients may have comorbidities associated with brittle diabetes or hepatobiliary dysfunction. While not absolute, general contraindications to lung transplantation are considered to be hepatic disease, severe renal dysfunction, and coronary or left ventricular heart disease not treatable with surgery or concomitant heart-lung transplant. Also of concern are those individuals with a history of malignancy. Those with a propensity for late recurrence of malignancy from any primary cancer should have a longer disease-free period before lung transplantation is considered. Several premorbid conditions have been noted to impact outcome among those receiving lung transplantation (139). Of interest to the rehabilitation community is the notion that premorbid functional status has been shown to be a strong predictor of survival among those receiving lung transplantation. Among those who require pretransplant invasive ventilation, 1-year posttransplant survival is less than 50% (137). Both morbid obesity and poor nutrition may result in increased morbidity and mortality. Almost one half of the patients with cystic fibrosis and obstructive lung disease presenting for transplantation have metabolic bone dysfunction (40). Those with severe osteopenia and osteoporosis may experience decreased quality of life. The role of living donor transplantation has continued to grow. When selecting donor sites among living donors, the lower lobe is often chosen because of anatomic considerations and functional capacity.

In the immediate postoperative period, attempts are made to limit peak ventilatory pressures to 35 mm Hg or less. Attempts are also made to quickly wean the patient from high  $\text{FiO}_2$  in order to reduce oxygen toxicity. Complications with the bronchial anastomosis can occur and tracheal dehiscence or airway necrosis will result in extensive pulmonary

compromise (141,142). Recent reports regarding the role of sirilomus in bronchial anastomotic complications have raised further concerns. Progressive strictures or bronchomalacia, can be common and is often recognized by direct visualization of a greater than 50% obstruction of the airway. Posttransplant bronchoscopy will focus on the evaluation of anastomotic areas and is often helpful in evaluating for secondary infection (141–144). Ischemia and/or reperfusion injury complicates some 15% of lung transplantations and is usually manifested early on (145,146). This syndrome appears to manifest itself in an adult respiratory distress syndrome (ARDS)-like fashion.

During the rehabilitation period, pulmonary artery thrombosis and deep venous thrombosis have been noted to occur in as many as 12% of lung transplant recipients (147). Chest CT imaging may provide a useful diagnostic adjunct (148). The possibility of neoplasm should be considered in the differential of slowly growing infiltrates in this population. Chronic rejection can be manifested by obliterative bronchiolitis (149,150). Those with obliterative bronchiolitis demonstrate significant decrements in FEV-1 and management is focused on progressive immunosuppressive therapies (150). Postoperative delirium has commonly occurred in lung transplant recipients, and appears to be associated with prolonged cardiopulmonary bypass, the administration of cyclosporine, and other nonspecific factors.

Primary bilateral lung transplantation or combined lung and heart transplantation interrupts the vagus nerve and thus the normal stretch receptor input. Despite this interruption, resting spirometry should retain a classical pattern similar to that of normal subjects. Perhaps more important is the fact that cough response to airway irritants is relatively impaired. Those receiving heart-lung or bilateral lung transplants achieve relatively normal total lung capacity, but this may be impaired secondary to sternotomy from the surgical transplantation procedure itself. Among those with single lung transplantation, final pulmonary function becomes rate limited by the function of the remaining diseased lung.

Fink has noticed that exercise capacity can increase up to 10 years post lung transplantation (151). Peripheral mechanisms have been suggested as a source of improvement in exercise capacity (152). Stable lung transplant patients often remain with exercise capacity deficits and much of this is secondary to expiratory and lower limb muscle weakness. Wang (153) has noticed that such persons have a lower proportion of type I fibers and that they have a higher lactate and inosine monophosphate ratios, indicating a greater dependence on anaerobic metabolism. Schwaiblmair evaluated 103 consecutive recipients of single-lung, bilateral lung, and heart-lung transplants. Cardiopulmonary exercise testing noted severe exercise intolerance and markedly impaired output parameters (153). Work capacity, oxygen pulse, tidal volume, and peak minute ventilation did not differ in patients following single, double-lung transplantation, or heart-lung transplants (154). These authors noted that despite the persistent limitations in aerobic capacity and work rate seen in many of the recipients, cardiopulmonary performance is reasonably well restored shortly after lung

and heart-lung transplantation, further suggesting a peripheral component to the exercise dysfunction (154).

Cardiopulmonary exercise studies of lung transplant recipients have found low maximum oxygen consumptions because of an as yet unexplained mechanism (155). A study of six lung transplant recipients and six age- and sex-matched, healthy control subjects were studied to assess the possibility of a mitochondrial myopathy in liver transplant recipients (155). The transplant group had significantly lower percent-predicted maximum oxygen consumption than the control group. The authors felt that liver transplant recipients have an impaired maximal exercise capacity because of a disorder of peripheral oxygen utilization (155). A proposed etiology is that this peripheral weakness may be caused by a cyclosporine-induced mitochondrial myopathy (155). Cardiopulmonary exercise studies of lung transplant recipients have found low maximum oxygen consumptions because of an as yet unexplained mechanism. A study of lung transplant recipients noted a significantly lower percent predicted maximum oxygen consumption than the control group and earlier onset of the anaerobic threshold (156). Lung transplant recipients also appear to have an impaired maximal exercise capacity because of a disorder of peripheral oxygen utilization, perhaps related to a myopathic component. Hall has suggested that exercise capacity is limited due to disorders of potassium regulation that explain the peripheral muscle weakness (157). Ross has noted persistent ventilation-perfusion ( $V/Q$ ) mismatches among those with lung transplantation during active exercise (158). Evans has also noted a persistent decrease in  $VO_{2max}$  after lung transplantation that may be related to abnormalities of skeletal muscle oxidative capacity (159). Such deficits may be long-standing and data suggested that after 6 and 12 months, indices of skeletal and respiratory muscle function and  $VO_{2max}$  improve further, but still remained lower than normal values (156). These authors concluded that in patients with heart-lung transplantation, skeletal and respiratory muscle function and exercise performance are reduced after surgery, and muscle function may improve with time but still appears impaired at 18 months.

Rehabilitation therapies offer techniques for enhanced coughing and mucociliary clearance, and providing treatment of the musculoskeletal system via exercise appears to enhance peripheral muscle capacity. Kesten (160) has suggested a pre-operative rehabilitation program for those awaiting transplantation. Those providing exercise and inpatient rehabilitation to such persons should be aware of the need for close oxygen monitoring, and frequent rest periods until capacity is increased. The rehabilitation environment should also have the capacity to deal with excess pulmonary secretions, as this is a potential cause of secondary complications. Stiebellehner et al. (161) performed a study of an aerobic endurance training program (AET) in comparison to normal daily activities to evaluate exercise capacity in lung transplant recipients. Nine lung transplant recipients were examined and all patients underwent incremental bicycle ergometry, identical exercise tests were performed after 11 weeks of normal daily activities

and then after a 6-week AET. Normal daily activities had no effect on exercise performance (161). The AET induced a significant decrease in resting minute ventilation and at an identical, submaximal level of exercise, a significant decrease in minute ventilation. Thus, in a carefully monitored setting an AET improves submaximal and peak exercise performance significantly.

### Heart Transplantation

Cardiac transplantation is a therapy of choice for end-stage heart disease. Despite major advances with organ preservation and immunosuppression, the physiology of the cardiac allograft is not normal and this decreases exercise tolerance and functional performance. The physiatrist should have a basic understanding of the major physiological changes after heart transplantation, the beneficial effects of exercise and indications for both immediate acute inpatient rehabilitation and long-term rehabilitation follow-up.

The most common indications for heart transplantation surgery are cardiomyopathy, end-stage coronary artery disease, and inability to be weaned from temporary cardiac-assist devices after myocardial infarction or nontransplant cardiac surgery (159). Recipient selection criteria are stringent and approximately one quarter of patients found suitable for transplants die of cardiac disease before a suitable donor organ becomes available. Left ventricular-assist devices and artificial hearts can be used as interim support. The heart is transplanted in an orthotopic position with aorta, pulmonary artery, and the pulmonary vein. Venous return is provided by a single anastomosis joining the retained posterior wall of the recipient's right atrium to that of the donor organ. More recently, the bicaval anastomosis technique has been used in performing heart transplantation (162). This technique differs from the standard mid-atrial anastomosis by keeping both atria intact and performing anastomoses in both the cava and pulmonary veins. This technique apparently avoids desynchronized atrial contractions and may improve cardiac performance by contributing more blood flow to the ventricles.

### Denervation

Cardiac transplantation involves removing the diseased heart and leaving an atrial cuff, which results in the complete denervation of the donor heart with loss of both parasympathetic and sympathetic nerve connections. With absent parasympathetic innervation, resting heart rate is elevated between 90 and 110 beats/minute due to the loss of vagal tone (162). The donor heart rate will not respond to vagolytic muscle relaxants, anticholinergics, anticholinesterases, digoxin, nifedipine, or nitroprusside (162). Impairments in chronotropic responsiveness and ventricular function due to surgical interruption of postganglionic sympathetic fibers have been regarded as the major reasons for diminished exercise performance (163). Since the resting heart rate is usually elevated, the resting stroke volume is therefore smaller than normal. The denervated heart requires mechanisms other than neural to maintain normal function during activities of daily living.

**TABLE 46.3 Summary of Precautions and Exercise Function During Early and Later Exercise Training Following Cardiac Transplantation**

<b>Routine Precautions During Initial Rehabilitation</b>	<b>Early Cardiovascular Changes</b>	<b>Later Cardiovascular Changes</b>
Sternal incision protection	Elevated resting heart rate	Improvement of exercise parameters with training
Cardiovascular monitoring using pulse rate, BP, pulse oximetry, and Borg rating of perceived exertion	Stroke volume increases before heart rate increases during exercise	Improvement in sympathetic tone to transplanted organ in some individuals
Ensure adequate preload	Delayed heart rate cool down after cessation of exercise	Improved left ventricular ejection fraction with training
Monitor for depression and other psychiatric symptoms, peripheral neuropathy, osteoporotic fractures	Decreased peak heart rate	Possible development of hypertension
Minimize exercise training during episodes of acute graft rejection	Decreased left ventricular ejection fraction	Possible development of coronary artery disease in transplanted heart

The Frank-Starling mechanism remains a major factor to maintain exercise performance in the transplanted heart (162). With this mechanism, increases in venous return allows for an increased preload that subsequently increases the left ventricular end diastolic volume to result in an increase in the stroke volume. Thus, the assurance of adequate preload is especially important after heart transplantation. With vigorous exercise, further increases of cardiac output are mediated by chronotropic and inotropic responses to circulating catecholamines (162). Heart rate continues to rise after cessation of exercise as a result of circulating catecholamines and in recovery, heart rate falls slowly as plasma catecholamines are metabolized (163). This contrasts to the normal innervated heart in which increases of stroke volume and heart rate occur simultaneously rather than sequentially.

While the effects of denervation after heart transplantation are well described, it has become increasingly clear that denervation is not a persistent phenomenon. Bengel et al. (164) using Positron Emission Tomography and a catecholamine analog technique demonstrated partial restoration of myocardial sympathetic innervation that correlated with improvements in the capacity for exercise. In 29 heart transplant recipients, increased sympathetic activity was significantly correlated with the change in global ejection fraction in response to stress. The improvements in chronotropic response to exercise resulted in significantly better exercise performance in those patients who had innervation compared to those who had persistent denervation without recovery of sympathetic tone (165).

Exercise performed 6 months after transplantation surgery can partially restore cardiac sympathetic innervation. Bernardi et al. (166) performed a randomized clinical trial using cycling at 60% to 70% of peak oxygen consumption for 5 days/wk for 6 months versus a control group. Using a novel clinical method of RR-interval changes during cyclical baroreceptor stimulation at different frequencies, it was demonstrated that low frequency stimulation induces cardiovascular changes via sympathetic nerve activity while higher frequency stimulation produces changes only from parasympathetic nerve activity (167).

Results from the randomized trial showed significant gains for trained subjects in peak oxygen consumption, exercise time, and maximal workload compared to controls. Autonomic testing performed at the conclusion of the trial showed only significant increases in the trained group with low frequency baroreceptor stimulation. This response was not present at baseline, indicating pure sympathetic reinnervation of the heart (Table 46-3).

When prescribing an exercise program, it is worthwhile to understand that resting heart rate is increased yet there is a delay in heart rate elevation when beginning vigorous activity and there is also delayed return of resting heart rate after cessation of exercise (162). From a practical perspective, heart transplant patients may require 6 to 10 minutes of steady work to increase heart rate compared to 2 to 3 minutes in subjects without a denervated heart. Isometric exercise in cardiac transplant patients does not increase the cardiac output because of denervation (166). However, there is an expected increase in blood pressure due to an increase in  $\alpha$ -adrenergic tone mediated by the central nervous system and not from increased circulating catecholamines.

Exercise training after heart transplantation increases the work capacity without increasing the peak heart rate. Yet, patients undergoing heart transplantation have preoperative inactivity and postoperative deconditioning that impacts exercise tolerance (167). One study estimates that the transplant patient have a 10% to 50% reduction in body mass due to prolonged preoperative physical inactivity combined with high corticosteroid administration (168). Consequently, maximal work output is reduced and maximal oxygen uptake is only two thirds of the normal age-matched population (169).

Although physical exercise has become an important part of the standard therapy for patients who have had an acute myocardial infarction and cardiac surgery, the role after heart transplantation has only recently been defined. In a randomized controlled trial, patients were enrolled approximately 2 weeks after transplantation surgery to an intensive rehabilitation protocol or to a control group that only received

written guidelines for exercise (170). The exercise program was multifaceted and included supervision by a physical therapist according to each patient's specific needs. Strengthening exercises consisted primarily of closed chain resistive exercises such as bridging, with lifting of the hips while keeping the knees in a flexed, supine position. Other activities included half-squats, toe raises, abdominal flexion and pelvic tilts. Flexibility exercises, which emphasize chest expansion and thoracic mobility included thigh stretches, trunk twists, scapular squeezes and shoulder rolls. Aerobic exercise consisted of walking on a motorized treadmill or paddling on a bicycle ergometer. The goal of this exercise training was at least 30 minutes of continuous exercise at moderate intensity. Patients visited a cardiac rehabilitation clinic one to three times per week but the authors did note that some were unable to attend more than once a week due to transportation difficulty and graft rejection. As noted previously, routine transvenous endomyocardial biopsy is used to diagnose rejection, because other signs and symptoms are often absent and rejection can be detected before graft function deteriorates. Patients who did have rejection were instructed not to exercise until follow-up endomyocardial biopsy showed resolution of rejection and that usually required 2 weeks. Before discharge from the rehabilitation protocol, patients of both groups received written guidelines, primarily focusing on active assisted range of motion exercises, flexibility, and lower extremity strengthening. Patients who participated in the exercise-training program increased their capacity for physical work as compared with controlled patients who did not undergo exercise training. Resistance exercise may also prevent glucocorticoid myopathy (171). Niset and Kavanagh (172,173) have also shown improvements in physiological parameters with a prescribed exercise program. Proximal weakness measured by sitting to standing rates improved in both the experimental and control groups between the baseline evaluation and the 6-month follow-up; the improvement among the exercising patients was almost three times as large. Exercise training is well tolerated and studies have not demonstrated higher incidence of rejection (163,166,171,174). The take home message is that exercise training should be considered standard postoperative care for heart transplant recipients.

Additionally, Joshi and Kevorkian (175) have detailed how inpatient rehabilitation can benefit cardiac transplant recipients. This study did include a selection bias to those with more severe complications and may not reflect the typical patient who receives a cardiac transplant. In this cohort, a number of secondary medical problems were noted during the inpatient rehabilitation protocol. Specifically, six out of twelve patients had hypertension, five of twelve had dysphagia, four of twelve had decubitus ulcers, three of twelve had peripheral neuropathy, three of twelve had elevated blood sugars, two of twelve had hemiparesis, and two of twelve had psychiatric disorders requiring antidepressant therapy. There was also one patient who sustained an osteoporotic vertebral compression fracture. Even with these deficits, significant gains in the Modified Barthel Index were documented (175).

The inpatient rehabilitation protocol should avoid strenuous upper limb exercises and teach proper positioning of the upper limbs during transfers or bed maneuvers. Specifically, patients should be instructed to keep their hands forward on the anterior thigh rather than reaching in an abducted arm posture to stabilize the upper torso during sit to stand maneuvers to minimize tension across the sternal incision (i.e., sternal precautions). In addition, patients should routinely have blood pressure, pulse rate, and pulse oximetry monitored during therapy. The Borg rating of perceived exertion can be used to keep the self-report below a rating of 13 ("somewhat hard") during exercise. Of the twelve patients in the Joshi and Kervorkian (175) series, ten were discharged to community with the remaining two discharged back to acute care because of medical or surgical complications. Patients in this study were also discharged from acute inpatient rehabilitation to phase-II and phase-III cardiac rehabilitation programs that share similarities to outpatient cardiac rehabilitation programs prescribed for patients recovering from myocardial infarction and coronary artery bypass grafting.

Lastly, patients may be seen in acute rehabilitation—patients who are long-standing cardiac transplant recipients, who are admitted for other diagnoses and then require rehabilitative services. It is important to remember that the development of coronary artery disease in the transplanted heart can be observed in 50% of recipients and the presence of ischemic cardiac disease should be considered when prescribing a rehabilitation protocol (176). Heart transplantation is a life-saving technique for those individuals with end-stage cardiac disease. Rehabilitation is extremely important and now is considered to be the standard of care postoperatively. It is important for the rehabilitation physician to understand the concept of the denervated heart and to realize that this state can improve over time via mechanisms that are not fully understood. Isometric and resistive exercise training is an important part of the rehabilitation protocol and has been shown to be safe in heart transplant recipients. Inpatient rehabilitation is useful for a subset of patients who are severely deconditioned or have other medical comorbid illnesses. Precautions should include routine measurement of cardiac parameters and avoidance of pressure at the sternal incision. Cardiac rehabilitation programs appear to be worthwhile not only in the acute phase but also in the more subacute phases of recovery to improve the overall work load and quality of life in these individuals.

## REHABILITATION ISSUES

### Deconditioning

Patients on a transplant waiting list are severely deconditioned from their underlying disease and associated adverse physiological effects of these diseases. For example, a typical patient with liver failure is a gaunt, cachetic, jaundiced, edematous, ascitic individual. Failure of this vital organ interferes with synthetic function (albumin, acute phase reactants, clotting factors) as well as metabolism of amino acids, glucose and fat,

making this patient malnourished, coagulopathic, edematous, and immunosuppressed. The combination of protein wasting (usually from muscle) and increased weight from edema and ascites is damaging to patient conditioning. Compounding this state is the mechanical impingement to respiration from the massive ascites among those with hepatic dysfunction. Many of these patients also have pulmonary and renal manifestation of liver diseases (hepato-renal syndrome, hepato-pulmonary syndrome) and often require prolonged intensive care stay while waiting for donor organs, further exacerbating an already suboptimal condition.

Similar states of severe deconditioning are also seen in patients with other end-organ failure—it is easy to imagine the result of short-gut syndrome (malnutrition), obliterative lung disease, and heart failure. Even among those with end-stage renal dysfunction who are on dialysis, are wrought with complications, such as anemia, poor healing, hypertension, and prolonged periods of inactivity related to frequent dialysis. In diabetics awaiting pancreas transplants, the insulin supplement does not replace all factors, however undefined, produced by this organ. Thus, these patients are also malnourished, and usually have associated morbidities such as atherosclerotic cardiovascular disease, and poor healing, both of which hinder postoperative recovery.

The very act of surgery itself is a physiologic demand on these patients. Transplantation surgeries are usually complex, time consuming, and associated with much blood loss. The long duration under anesthesia and the paralysis of the patient in a single position, no doubt has physical implications with regard to postoperative deconditioning and rehabilitation. Similarly, cardiopulmonary bypass in lung and heart transplant creates additional stresses on a patient. The inexorable catabolic state seen in all postoperative surgical patients further weakens an already malnourished and protein-depleted patient (see Fig. 46-1).

In order to combat the severe deconditioning described above, initial rehabilitation requires a progressive rehabilitation program that begins with initial remobilization. Standing frames are useful to build endurance in deconditioned patients who exhibit proximal weakness. Tilt tables can be helpful to adapt postural reflexes for patients who have been recumbent for many months while in acute care.

### Neurocognitive Concerns

Persons receiving transplantation have been noted to experience a variety of neurocognitive dysfunctions. Ghaus et al. (177) performed a study to evaluate such concerns among those with liver transplantation. They reviewed 41 consecutive patients who had 45 procedures associated with liver transplantation. Encephalopathy occurred after 28 procedures (62%) with immediate onset and no significant recovery before death or retransplantation in 11 (24%), slow recovery in eight (18%), and delayed onset (1 to 50 days, average 11) in six (13%) (177). Intermittent confusion and agitation with full recovery followed three, and focal and generalized seizures followed five (11%) procedures with multifocal myoclonus in two and

status epilepticus in one. Isolated focal seizures followed two and myoclonus or unclassified seizures, one each. All patients with seizures had encephalopathy. Brain imaging showed atrophy in three instances, intracerebral haemorrhage in two, multiple infarctions in one, and intracerebral and subarachnoid haemorrhage with infarction in one. Cerebrospinal fluid analysis showed increased protein in three subjects. Neurological complications after transplantation were associated with increased mortality (177). Postoperative hypomagnesemia was associated with the development of nervous system complications. In another study of 40 persons who received liver transplantation, Buis (178) noted transient confusion among 48% of those receiving transplantation for alcoholic liver disease but only 6% of those who required transplantation secondary to hepatitis C. Studies of diffusion weighted imaging and recovery imaging (FLAIR) have noted hyperintense lesions. Psychologic consequences such as depression of transplantation are also an important consideration for the rehabilitation team. Such persons often benefit from psychologic evaluation while in rehabilitation. Rothenhausler (179) performed a study of 75 subjects to explore the prevalence of psychiatric disorders among orthotopic liver transplantation recipients, and to investigate how psychiatric morbidity was linked to health-related quality of life (HRQOL). Psychiatric morbidity was assessed using the Structural Clinical Interview for the DSM-III-R. A probable psychiatric diagnosis, according to DSM-III-R, was noted in 22.7% of the sample, 2.7% had full posttraumatic stress disorder (PTSD), 2.7% major depressive disorder (MDD), and 16% partial PTSD. Patients with PTSD symptoms demonstrated lower cognitive performance, higher severity of depressive symptoms, and more unfavorable perception of social support (180). Liver transplant-related PTSD symptomatology was associated with maximal decrements in HRQOL. The duration of intensive care treatment, the number of medical complications, and the occurrence of acute rejection were positively correlated with the risk of PTSD symptoms subsequent to liver transplantation (179). Neuropsychological performance is also an important consideration after transplantation. Temple et al. (180) examined the relationship between cardiac function and cognitive test performance among candidates for heart transplant. Increasing hemodynamic pressure variables, such as pulmonary artery systolic pressure, were associated with decreased cognitive performance on a measure of psychomotor speed and attention. In contrast, cardiac output and cardiac index appeared to not be significantly related to cognitive performance (173). Of note, these authors found that poor performance on cognitive tests among heart transplant candidates appears to be attentionally mediated (180). Activities of daily living are often impacted by cognition disorders after transplantation. Putzke (181) evaluated the ability of patients with heart transplant to perform day-to-day tasks (e.g., medication management, dietary regulation). They studied a series of 75 heart transplant candidates and 38 controls to examine the predictive validity of demographic, neuropsychologic, and cardiac function variables to a performance-based measure of instrumental activities of

daily living capacity. The instrumental activities of daily living capacity were most consistently predicted by long-standing verbal ability and psychomotor speed and mental flexibility. In contrast, cardiac function measures (e.g., cardiac output, mean atrial pressure) were largely unrelated to the patient's activities of daily living performance (181).

### Neuropathy and Myopathy

Severe acute polyneuropathy, complicating transplantation is not uncommon. Rezaiguia-Delclaux (182) reported three cases of severe acute motor deficit after orthotopic liver transplantation. In a context of graft dysfunction, these patients developed acute tetraplegia concomitant with early allograft failure. In these three patients, electrophysiological signs of sensorimotor axonal polyneuropathy were found.

El-Sabroul noted that peripheral neurological complications occur frequently in solid organ transplant recipients. Recent evidence supports the role of the immune system in initiating and perpetuating the ongoing neural damage in this entity. Infectious agents may initiate the immune attack, and these authors reported a series of transplant patients with a Gullian-Barre-like syndrome associated with CMV (183). Cyclosporine has now also been associated with a generalized sensorimotor neuropathy (184). An important consideration has been the improvement in function that may occur after transplantation. A study of nerve conduction velocity changes among patients with severe liver syndrome was performed by Lee et al. (185). Twenty-five patients admitted for a liver transplantation were involved in this study. All patients underwent nerve conduction study before liver transplantation and 6 months after liver transplantation. The sensory amplitudes and motor conduction velocities substantially increased after transplantation (185).

Immunosuppressive medications have also been associated with acute myopathy and exercise impairment (186). Critical illness myopathy has been associated with those receiving liver transplant and acute myopathy posttransplant has been reported to produce a tetraplegia-like picture (187). Campellone (188) reviewed the problems associated with acute myopathy among transplant recipients. One hundred consecutive adult patients were prospectively assessed for muscle weakness after orthotopic liver transplant. Electrodiagnostic studies and muscle biopsies were performed on consenting affected patients. Seven patients developed acute persistent weakness after orthotopic liver transplant. Electrodiagnostic studies were consistent with a necrotizing myopathy. In another study, histopathologic evaluation in five subjects revealed a necrotizing myopathy with loss of myosin thick filaments (187). A higher initial index of illness severity, dialysis requirement, and higher doses of glucocorticoids were associated with the development of myopathy. Patients with myopathy subsequently remained in the intensive care unit longer than unaffected patients. Stephenson et al. performed a study to determine the exercise impairment that occurs in liver transplant recipients. They noted that liver transplant recipients exhibit impaired peak exercise performance, similar to that observed after

other solid organ transplants, probably as a result of chronic deconditioning or myopathy related to immunosuppressive medications (189).

### QUALITY OF LIFE ISSUES

The initial focus in organ transplantation clinical research was demonstrating acceptable technical and survival outcomes. However, quality of life posttransplantation has now become an important parameter. Bucuvalas (190) performed a study of 77 pediatric liver transplant recipients ages 5 to 18 years, all of whom had had liver transplant at least 6 months previously. These authors evaluated quality of life issues. HRQOL in pediatric liver transplant recipients was lower than that reported for healthy children but similar to that for children with other chronic illness. Age at transplantation and maternal education predicted psychosocial function. HRQOL was decreased in a population of pediatric liver transplant recipients compared with the general population and similar to that for children with chronic illness. Forsberg et al. (191) performed a study of the coping strategies of adult liver transplant recipients. The group showed a homogeneous pattern of change in coping strategies. This prospective study indicated that coping style changed primarily at an individual level during the first year after liver transplantation while changes in coping strategies, were not common for the group. The usual coping strategy during the first posttransplant year was confrontational coping. A German study evaluated the quality of life among those who had participated as living related liver donors for liver transplant 1 year after surgery (192). Donors viewed living related liver transplant positively. Quality of life after donation did not change. However, donors had a prolonged period of physical rehabilitation, and 41% experienced financial disadvantages (Fig. 46-2).

**FIGURE 46-2.** Evaluation process.

## NOVEL CONCEPTS

Recent advances have allowed for the transplantation of neural and cartilaginous tissues with early success. Bentley (193) has recently described a randomized study demonstrating the potential efficacy of chondrocyte implantation in the knee. Mensical allograft transplantation appears efficacious among younger patients with focal knee dysfunction (194). These tissues are unique in that they appear to be privileged, and thus do not require extensive immunosuppression.

Partial facial transplantation may become an important option for those with severe deforming facial injuries or burns. Partial facial composite transplantation of the lower two thirds is technically feasible (195). These procedures raise ethical and immunological issues.

Kondziolka and Meltzer (196–198) have described neuronal transplantation in humans for chronic motor dysfunction following stroke. These preliminary studies have noted clinical improvements in motor function and integration of the neuronal transplant when assessed via imaging techniques. Several authors have postulated the potential role that neuronal transplantation may have in the treatment of spinal cord injury (199–201). The role of these implants may be via direct in-growth or perhaps via neurotrophic growth factors. The rehabilitation of persons with neurologic and musculoskeletal disorders may be changed by these novel transplantation concepts in the near future.

## Tolerogenic Therapy

The holy grail of transplant medicine has been the idea of tapering or eliminating immunosuppressive therapy. The primary concept is to be able to reduce or eliminate the need for immunosuppressive therapy. Some have felt that the regulation of dendritic cells, which are the inducers of immune reactivity, is an important key (202). In a study by Starzl, 82 patients who had received kidney, liver, pancreas, or intestinal transplant had immunosuppressive pretreatment and subsequent dose spacing. They noted immune activation in graft biopsy samples but function was mostly maintained upon tapering of immunosuppression (203). Others have advocated the use of a nonmyeloablative preparative regimen in an attempt to achieve transient chimerism and thus eliminate the need for immunosuppressive therapy (204).

## CONCLUSION

Transplant medicine has made tremendous strides during the last 30 years. Persons surviving transplantation are often left with neuromusculoskeletal disorders that require rehabilitation intervention. Many of the associated complications of transplantation are mediated via immunosuppressive therapy. Novel concepts such as tolerogenic therapy may help to moderate such effects. The rehabilitation specialist will continue to play a key role in helping to ameliorate the mobility and cognitive issues associated with solid organ transplant.

# Rehabilitation of the Individual with HIV

## INTRODUCTION

The quest for effective treatment, prevention, and cure of the acquired immunodeficiency syndrome (AIDS) has resulted in one of the most concentrated research efforts in the history of medicine. Since its discovery in the early 1980s, the human immunodeficiency virus (HIV) has become one of the most studied of human pathogens. Although an outright cure for AIDS still seems to be a distant dream, developments have been breathtaking and, as of the time of this writing, the possibility of controlling the progression of HIV infection, preventing the decline in immune function that leads to AIDS, and enabling the reconstitution of the immune system destroyed by the virus, is within grasp. An effective vaccine, however, remains elusive.

HIV is important to the field of rehabilitation for two reasons: its occurrence in traditional rehabilitation patients and it can, in and of itself, result in disability. HIV is among the differential diagnosis of many disorders commonly seen in rehabilitation settings. In patients with known HIV infection, rehabilitation professionals need to be familiar with the many chemotherapeutic agents commonly used for treatment and with their side effects and drug interactions. This last task is particularly daunting given the accelerated process for U.S. Food and Drug Administration (FDA) review and approval of new treatments.

This chapter emphasizes the nature of HIV and the many ways that it can cause disability. Current medical treatment strategies are also discussed. However, the discussion is not intended to be comprehensive, and interested readers are urged to follow the literature closely and keep up to date in this rapidly evolving field. The medical management of HIV disease and its complications should be left to experts. Rehabilitation strategies used to manage functional impairments typical of those found in association with HIV, such as spinal cord injury, brain injury, neuropathies, and rheumatologic disorders, however, are similar to those used in disability resulting from other causes, as discussed elsewhere in this book.

## HIV-RELATED DISABILITY

The full extent of disability resulting from HIV is unknown. One of the earliest studies attempting to evaluate this, the NIH retrospective study, looked only at individuals with AIDS

who were involved in research protocols and were referred for various rehabilitation interventions (1). A more comprehensive prospective study of disability in a population of men with HIV was obtained as part of the AIDS Time-oriented Health Outcome Study (ATHOS) (2,3). Of those individuals with AIDS, more than 50% reported difficulty with one or more instrumental ADLs, such as grasping and driving, nearly 30% with basic ADLs, such as bathing and dressing, and more than 40% with basic mobility. Even among symptomatic seropositive individuals without AIDS, nearly 30% reported difficulties with instrumental ADLs, more than 10% with basic ADLs and 15% with basic mobility. With the introduction of highly active antiretroviral therapy (ART, formerly HAART), it has become possible to control and even reverse the progression of HIV. Although functional abilities generally improve with treatment, some degree of functional impairment often remains, and continued functional decline has been reported (4–8). Quality-of-life issues have also become more significant as survival improves (9–11).

## NATURAL HISTORY OF HIV

### Pathogenesis

HIV type I infection (HIV-1), the most prevalent form of the virus, results in the destruction of CD4-positive lymphocytes, leading to a decline in their numbers. In acute primary infection, HIV-1 replicates briskly and viral titer rises rapidly (12–14). Within 1 week of onset,  $10^5$  to  $10^7$  infectious particles per microliter of plasma can be measured (15,16). Fifty to seventy percent of patients experience a clinical syndrome, which may include fever, rash, sore throat, lymphadenopathy, splenomegaly, myalgias, arthritis and, rarely, meningitis.

Within a few weeks to months, seroconversion occurs and HIV-1 antibodies can be measured by the enzyme-linked immunosorbent assay (ELISA) and Western blot tests. Rapid viral replication persists, however, in the bloodstream, lymphoid tissue, and central nervous system (CNS) leading to a high turnover of infected cells (13,17). A steady state of plasma HIV ribonucleic acid (RNA) level is established within 6 to 12 months of seroconversion, and measurements of the viral load are prognostic (18,19). Levels of  $10^6$  HIV-1 RNA copies or greater per microliter of blood correlate with rapid

**TABLE 47.1** Classification of HIV

CD4 Cell Count	Group A: Asymptomatic, Acute HIV, or Generalized Lymphadenopathy	Group B: Symptomatic, not A or C	Group C: Indicator Conditions Present
≥500/mm <sup>3</sup>	A1	B1	C1*
200–499/mm <sup>3</sup>	A2	B2	C2*
<200/mm <sup>3</sup>	A3*	B3*	C3*

\*Indicates the presence of AIDS.

progression over a few years,  $10^3$  to  $10^5$  with progression in 8 to 10 years and less than  $10^3$  with nonprogression (20). Unfortunately, rapid viral turnover and mutation lead to the appearance of resistant strains if viral suppression is not complete (21–23).

### Classification

The Centers for Disease Control and Prevention (CDC) developed a revised classification scheme in 1993 based on the development of signs and symptoms and the CD4 lymphocyte count (24). The classification was revised again in 1999, allowing HIV-seropositive individuals without other AIDS-defining conditions to be reported (25). This scheme is summarized in Table 47-1. Group A patients are seropositive but essentially symptom free. Group C patients have one or more AIDS-indicator illnesses. A comprehensive list of AIDS-indicator conditions is beyond the scope of this chapter, but suffice it to say that they include most opportunistic infections and malignancies, HIV dementia, and the AIDS wasting syndrome. Group B patients have early symptoms of immune deficiency in the absence of an AIDS-indicator condition. Patients are further subdivided into categories 1, 2, and 3, corresponding to CD4 counts of 500/mm<sup>3</sup> or above, 200 to 499, and less than 200, respectively. Patients falling into either group C or category 3 are classified as having AIDS.

### Demographics

The World Health Organization (WHO) estimates that as of December, 2007, 30.8 million adults and 5 million children worldwide are living with HIV-1 infection. Half of those infected are women. HIV continues to run rampant in less developed areas of the world, particularly in sub-Saharan Africa and Southeast Asia, in spite of efforts aimed at prevention (26). About 1.3 million people are infected with HIV in North America. In the United States, there are now about 17,000 deaths annually and in 2005, among persons with HIV, 20% were female, 35% white, 44% black, and 19% Hispanic, reflecting the continuation of a significant shift into minority populations (27).

### Documented Routes of Transmission

Documented routes of transmission include sexual contact with infected individuals, percutaneous or mucous membrane exposure to infected blood or body fluids, or

transplacental, perinatal, or breast milk transmission from mother to infant. In 2005, of 322,000 HIV-positive men in the United States, 59% were exposed through male-to-male sexual transmission, 20% through intravenous drug use, and 11% through high-risk heterosexual sex. Of the 96,000 women, 65% contracted HIV through high-risk heterosexual exposure and 35% through intravenous drug use (27).

### Occupational Exposure

The risk of HIV-1 infection is estimated to be 0.3% after percutaneous injury involving infected blood (28) and 0.1% after mucous membrane exposure (29). Universal precautions should be used at all times that contact with blood or body fluids may be anticipated. These include the use of gloves to prevent potential exposure to infectious body fluids or broken skin during procedures such as wound care and electromyography (EMG), and the use of a gown, goggles, and a mask during procedures in which spattering of blood is possible.

Postexposure prophylaxis (PEP) is recommended for percutaneous or mucous membrane exposure to blood or visibly bloody fluid, semen, vaginal secretions, cerebrospinal, synovial, pleural, pericardial, and amniotic fluids. In a case control study, postexposure zidovudine decreased HIV-1 infection by 81% (30). Recently updated guidelines by the New York State Department of Health recommend initiating PEP as soon as possible after it has been determined that an exposure has occurred, ideally within 2 hours and not later than 36 hours. The combination of Combivir with tenofovir is one preferred regimen, but consultation with an HIV specialist is highly recommended in order to choose a regimen based on the source patient's HIV strain and antiretroviral resistance, if known (31). A national PEP line is maintained by the University of California, San Francisco (<http://www.ucsf.edu/hivcntr/PEPline/>) 1-888-448-4911. Expert clinicians are available 24 hours a day, to offer advice in the event of an exposure. Nevirapine is not recommended for PEP due to the incidence of severe hepatitis (32). A medical evaluation, counseling, and follow-up by an experienced physician should be provided promptly, but initiation of PEP should not be delayed (33,34) <<http://www.hivatis.org/>>. Recommendations for pregnant health care workers are similar except that efavirenz and amprenavir should be avoided (35,36).

### Prevention of Transmission Among the Disabled

One of the most significant things rehabilitation professionals can do to stop the spread of HIV is to educate their patients as to the modes of transmission and means of preventing transmission. High-risk behaviors must be strongly discouraged, and education in safer sex practices should be included as part of all discussions on sexuality.

The most effective protective measure is the use of a barrier device whenever contact with infectious fluids is anticipated. This includes the use of condoms, the dental dam for oral sex, and the use of gloves or a finger cot for digital anal penetration. Safe touching should be substituted for scratching, biting, and abrading activities that might lead to inadvertent fluid exposures. Water-soluble lubricants should be used particularly in insensate areas to reduce the likelihood of inadvertent abrasion. Mutual masturbation may be suggested as an activity that is virtually risk-free. Patients should be reminded to clean and disinfect all enrichment aids (sex toys) using a solution such as 10% chlorine bleach.

When patients experience direct exposure to infectious fluids, prophylaxis should be offered as it is to health care workers. Because about a fourth of children delivered vaginally to untreated infected mothers will also be infected, prophylaxis should also be used to reduce vertical transmission. A prospective trial showed that pregnant women who took zidovudine could decrease the risk of perinatal transmission by 67% (37,38), and several subsequent trials have shown that the risk of mother-to-child transmission can be reduced substantially by perinatal treatment of both mother and neonate (39,40). Prevention of transmission in the adolescent patient demands particular attention (41). The avoidance of HIV transmission among patients who lack the capacity to modify their behavior, such as brain-injured individuals with impaired impulse control, remains a difficult area without clear-cut solutions (42,43).

## CLINICAL EVALUATION OF HIV

### Serologic Testing

The mainstay of HIV-1 testing involves screening for anti-HIV-1 antibodies with the ELISA, with the Western blot test used for confirmation. Serologic testing can only detect infection after seroconversion has occurred, which may take up to 3 to 6 months after acute infection. When ELISA screening and confirmatory Western blot testing are used, the false-positive rate is negligible. Pre- and post-test counseling are advisable to educate patients about the need for repeat testing, as well as modification of high-risk behaviors and, in the event of a positive test, the need to seek specialized medical care. Home test kits, in which samples of saliva, blood, or urine can be collected by the patient at home or in a doctor's office and sent directly to testing laboratories, are available. Recently, the CDC has endorsed routine testing for HIV in medical settings with an opt-out clause. This policy change is hoped to help identify patients with HIV who may otherwise not have

sought testing or whose physicians may not have thought were at increased risk (44).

### Evaluation of the Seropositive Patient

It is particularly important to identify seropositive individuals both because medical therapy for HIV is highly beneficial and in order to identify the individuals at risk for spreading the infection to others. In patients with unexplained sweats, fevers, or weight loss, skin lesions characteristic of opportunistic infections or malignancy, dyspnea unrelated to intrinsic cardiac or pulmonary disease, or altered neurologic function not attributable to a specific lesion, injury, or toxin, HIV infection must be considered in the differential diagnosis. The presence of other sexually transmitted diseases (STDs) also should be considered an indication for HIV testing. Even the presence of diseases seen at higher rates in HIV patients, such as tuberculosis (TB), should be considered an indication for testing.

The physical exam should focus on findings often seen in association with HIV. The skin and oral cavity should be carefully examined for mucocutaneous lesions, particularly those associated with Kaposi's sarcoma (KS). Lymphadenopathy and hepatosplenomegaly are also important indicators. Because of the propensity of HIV to involve the nervous system, a detailed neurologic examination is essential. Peripheral neuropathies, cognitive disorders, myelopathy, and focal CNS dysfunction may all be seen in association with HIV. Although cognitive dysfunction is not common prior to the development of AIDS, a neuropsychologic evaluation is helpful to establish a baseline.

The laboratory evaluation should include routine chemistries and a complete blood count. A mild increase in transaminases may be seen, along with an elevated erythrocyte sedimentation rate, anemia, and general cytopenias. Serum protein electrophoresis may demonstrate an increase in immunoglobulins. Lymphocyte evaluation may demonstrate a decrease in CD4-positive lymphocytes or a reversal in the CD4/CD8 ratio. Viral load tests such as the polymerase chain reaction (PCR) or branched deoxyribonucleic acid (DNA) are important for establishing prognosis and for evaluating the effectiveness of antiretroviral treatments.

## TREATMENT STRATEGIES IN AIDS

Because clinically latent stages of HIV-1 infection involve rapid viral replication, strategies now aim to decrease steady-state viral RNA levels. The benefits of decreasing HIV viral load must be weighed against side effects and the risk of developing resistant strains (45,46). Published guidelines are meant to be interpreted by specialized providers <<http://www.hivatis.org>> (47,48). In general, the aim is to start antiretroviral medications before complications related to immunosuppression occur and when the patient can achieve maximum adherence. Medications commonly used in HIV along with some of their indications and side effects are summarized in Table 47-2. Numerous important side effects and drug interactions may

TABLE 47.2 Common Drugs Used in HIV

Drug	Common Usage	Side Effects	Drug Interactions
<i>Antiretrovirals (nucleoside analog RT inhibitors)</i>			
Zidovudine (AZT)	Used in combination	Nausea, headache, fatigue, anemia, neutropenia, myopathy	Increased hepatotoxicity of amphotericin B, ganciclovir
Didanosine (ddI)	Used in combination	Painful neuropathy, pancreatitis, mitochondrial toxicity, lactic acidosis	May decrease absorption of other drugs
Zalcitabine (ddC)	Rarely used due to toxicity	Painful neuropathy, pancreatitis, oral ulcers, granulocytopenia, rash, fever, hepatitis	Increased toxicity with foscarnet and valproic acid; alcohol may increase risk of pancreatitis
Lamivudine (3TC)	Used in combination	GI intolerance	
Emtricitabine (FTC)	Used in combination	GI intolerance	
Abacavir	Used in combination	GI intolerance, hypersensitivity reaction may be fatal, Increased risk of MI (308)	
Stavudine (d4T)	Rarely used due to toxicity	Painful neuropathy, hepatic dysfunction, mitochondrial toxicity, lactic acidosis	
<i>Antiretrovirals (nucleotide analogue RT inhibitors)</i>			
Tenofovir	Used in combination	GI side effects	
<i>Antiretrovirals (nonnucleoside analogue RT inhibitors)</i>			
Efavirenz	Used in combination	Rash, neurologic and sleep disturbances, lipid abnormalities	Many drug interactions, may decrease PI levels
Nevirapine	Used in combination	Rash, hepatitis	May decrease protease inhibitor levels
Delavirdine	Used in combination	Rash	May decrease didanosine levels
Etravirine	Works in NNRTI-resistant virus	Rash	
<i>Antiretrovirals (protease inhibitors)</i>			
Saquinavir	Used in combination	GI distress, elevated LFTs	Decreased bioavailability of Ca channel blockers
Indinavir	Used in combination	Hepatotoxicity, nephrolithiasis, glucose intolerance	As above, plus increased desipramine, rifabutin, ergotamine, and amiodarone levels; prolonged sedation with midazolam and triazolam; decreased OCP effectiveness; fatal arrhythmias with astemizole
Ritonavir	Used to boost other PI levels	GI upset, perioral paresthesias, alteration of taste, headache, elevated LFTs, lipid abnormalities	Similar to indinavir, but may be more pronounced, failure of oral contraception, multiple P450 interactions—most potent P450 CYP3A inhibitor decreases some drug levels
Nelfinavir	Used in combination	Diarrhea, lipid abnormalities	
Ampronavir	Used in combination	GI disturbance	
Fos-ampronavir	Prodrug of ampronavir	GI disturbance	
Lopinavir/ritonavir	Used in combination	GI disturbance, glucose intolerance, lipid abnormalities	See ritonavir
Atazanavir	Used in combination		Contraindicated with proton pump inhibitors and interacts with H2 blockers.
Tipranavir	Used in combination	Hyperbilirubinemia	
Darunavir	Used in combination	GI disturbance	Multiple, difficult to predict
		GI disturbance	

<i>Antiretrovirals (novel agents)</i>			Injection site reactions	Multiple
Enfuvirtide	Fusion inhibitor			
Maraviroc	CCR5 entry inhibitor		Hypotension	
Raltegravir	Integration inhibitor		Elevated CK	
<i>Combination agents (names outside the United States may differ)</i>				
Combivir	Zidovudine + lamivudine		Similar to individual components	Similar to individual components
Epzicom	Abacavir + lamivudine		Similar to individual components	Similar to individual components
Trizivir	Zidovudine + lamivudine + abacavir		Similar to individual components	Similar to individual components
Truvada	Tenofovir + emtricitabine		Similar to individual components	Similar to individual components
Atripla	Tenofovir + emtricitabine + efavirenz		Similar to individual components	Similar to individual components
Kaletra	Lopinavir + ritonavir		Similar to individual components	Similar to individual components
<i>Prophylactic agents</i>				
Trimethoprim/sulfamethoxazole	PCP prophylaxis and treatment, toxoplasmosis prophylaxis		Rash, fever, neutropenia, thrombocytopenia, hepatitis, headache, meningitis, hyperkalemia	Potentiation of coumadin, oral hypoglycemics and, phenytoin; decreased effectiveness of cyclosporine
Dapsone	PCP prophylaxis		Rash, fever, hemolysis in G6PD deficiency	ddl decreases absorption; decreased effectiveness of oral contraceptives
Pentamidine	PCP prophylaxis and treatment		Aerosol: bronchospasm; IV: nephritis, pancreatitis, hypoglycemia, rash, neutropenia	Renal failure with Amphotericin B; hypocalcaemia with foscarnet
Rifabutin	MAC prophylaxis		GI, auditory, iritis	Decreases levels of guanidine, oral contraceptives, phenytoin, methadone, digoxin, cyclosporine, azoles, corticosteroids, beta blockers
Azithromycin	MAC prophylaxis		GI upset	
<i>Common treatments</i>				
Acyclovir	Herpes simplex, zoster		Diarrhea, phlebitis (IV)	
Ganciclovir	CMV		Neutropenia, GI	
Foscarnet	CMV		Nephrotoxicity, seizure, nausea, hypomagnesemia, calcemia and natremia, nephrotoxicity, headache	Increased nephrotoxicity with cyclosporine
Cidofovir	CMV		Nephrotoxicity	Hypocalcemia with pentamidine
Fluconazole	Antifungal: candida and cryptococcus		Hepatotoxicity, nausea, rash	Decreased absorption with cimetidine; decreased levels with carbamazepine and rifampin; increases phenytoin levels
Ketoconazole	Antifungal: candida		GI upset, pruritis, headache, rash	Fatal arrhythmias with terfenadine and astemizole; decreases rifampin; potentiates coumadin
Itraconazole	Antifungal: histoplasmosis, aspergilla		Hepatitis, GI upset, rash headache	Fatal arrhythmias with terfenadine and astemizole; decreased levels with carbamazepine; increased sedation with midazolam
Amphotericin B, Liposomal amphotericin B	Antifungal: serious fungal infections		Nephrotoxicity, fever, chills, hypomagnesemia, hypocalcemia	Dosage must be adjusted in renal failure

CMV, cytomegalovirus; IV, intravenous; LFT, liver function test; MAC, *Mycobacterium avium* complex; OCP, oral contraceptive preparation; PCP, *Pneumocystis carinii* pneumonia.

occur that may limit effectiveness or tolerability of therapy, or result in dangerous iatrogenic complications and disability (49,50).

### Antiretroviral Agents

Combination therapy with three or more active antiretroviral agents in order to achieve an undetectable HIV viral load in plasma has become the standard of care. Usual combinations consist of two nucleoside analogue reverse transcriptase (RT) inhibitors plus a protease inhibitor or nonnucleoside analogue RT inhibitor. Other combinations can also be effective; however, numerous clinical trials have demonstrated the emergence of resistant strains with monotherapy and dual therapy (51–53).

#### RT Inhibitors

In 1987, the FDA approved zidovudine (AZT), a nucleoside analog RT inhibitor. Subsequently approved were other nucleoside analogs, including didanosine (ddI), zalcitabine (ddC), stavudine (d4T), lamivudine (3TC), emtricitabine (FTC), abacavir, and the nucleotide analogue RT inhibitor, tenofovir (54–58). These agents act by inhibiting the process of reverse transcription, preventing viral RNA from being transcribed into cellular DNA. Currently, there are four nonnucleoside analogue RT inhibitors approved in the United States. These are efavirenz, nevirapine, delavirdine, and etravirine. As with the nucleoside analogues, they can be highly effective in suppressing the HIV viral load when used in combination with other agents (59–63).

#### Protease Inhibitors

As of this writing, ten protease inhibitors have been approved by the FDA for HIV infection: saquinavir, indinavir, ritonavir, nelfinavir, amprenavir, fos-amprenavir, lopinavir, atazanavir, tipranavir, and darunavir (57,64–68). These result in the production of immature, noninfectious HIV-1 particles by blocking the cleavage of HIV-1 polyproteins into component proteins. Combinations of protease inhibitors and RT inhibitors have been shown to reduce plasma HIV-1 RNA levels below detectable levels and to reduce morbidity and mortality. The protease inhibitors are often “boosted” to higher plasma levels by addition of low-dose ritonavir, which is a potent inhibitor of the cytochrome p450 system.

#### Novel Agents

Currently, there is one fusion inhibitor, enfuvirtide, approved for use by the FDA. This polypeptide binds to GP41 transmembrane protein on the HIV virion and prevents the conformation change required to fuse the virion with the CD4 cell membrane thus inhibiting viral entry. It is injected subcutaneously and thus is most often used in patients who have developed resistance to other agents (69).

In August 2007, the first CCR5 antagonist entry inhibitor was FDA approved in the United States. CCR5 is one of the coreceptors that HIV commonly uses to bind and enter CD4-positive T-cells. Maraviroc acts as a CCR5-binding antagonist that blocks HIV entry into the cell. Since some strains of HIV

can use a different co-receptor (CXCR4), a test must first be run to determine if the individual patient’s strain of HIV contains CXCR4 variants, prior to use of CCR5 antagonists (70).

In October 2007, the first integrase inhibitor, raltegravir, was FDA approved for use in the United States. This antiretroviral blocks a step of HIV viral replication after reverse transcription, in which the viral DNA integrates into the host cell genome.

The availability of the new classes along with improved resistance profiles of some of the new agents in older classes of antiretrovirals has recently led to the exciting possibility of controlling viral replication in patients who previously had virus resistant to all available ART.

### Immune Stimulants

Cytokines have been used in clinical trials to stimulate production of CD4 cells (71). Interleukin-2 can stimulate CD4 cell production, but it also increases virus production. The use of stimulating cytokines in conjunction with potent antiretroviral combinations is effective but is not often necessary.

## COMMON CAUSES OF DEBILITY

Although HIV itself is felt to be responsible for many forms of functional compromise, particularly in the CNS, a large number of disabling syndromes are associated with opportunistic infections and malignancies. The following sections are organized by the types of impairment syndromes that result and, to the extent practical, in order of the timing of their appearance in HIV infection. A summary of these is listed in Table 47-3.

### Respiratory Compromise and Disseminated Infection

#### Pathogenic Fungi

Endemic pathogenic fungi such as *histoplasma capsulatum*, *blastomyces dermatidis*, and *coccidioides immitis* can cause disease in normal hosts and particularly in HIV infection and AIDS. Patients often present with slowly progressive wasting, fevers, weight loss, or ulcerations of skin. Bone marrow dysfunction may occur and, occasionally, disseminated intravascular coagulation and death. The chest x-ray may be normal or show a progressive infiltrate. The serum test for *histoplasma* polysaccharide is specific and sensitive. Treatment consists of induction with amphotericin B and maintenance with itraconazole (72,73).

#### Mycobacterium TB

TB caused by *mycobacterium TB* (mTB) is common and severe, and seen early in the course of AIDS, often at CD4 counts above 200 cells/ $\mu$ L (74,75). Symptoms may be subtle. TB may disseminate to a wide variety of organs including the brain and spine. Guidelines for the diagnosis, treatment, and prophylaxis of infectious TB have been detailed by the CDC and elsewhere (76–79). Of concern, however, are outbreaks of multi-drug-resistant TB (80,81).

***Pneumocystis Jiroveci* Pneumonia (PCP)**

*Pneumocystis jiroveci* (formerly *Pneumocystis carinii*) is a fungus-like pathogen that causes PCP, the most common AIDS-defining illness in the United States, accounting for about 18% of cases (82,83). Seen throughout the course of the disease, symptoms may develop gradually and include dyspnea on exertion, shortness of breath, cough, weight loss, fevers, and night sweats. The chest x-ray may show a diffuse alveolar infiltrate and serum lactate dehydrogenase (LDH) may be elevated. Diagnosis is most often made by identification of *Pneumocystis* organisms in expectorated sputum or from bronchoscopic specimens.

A room air blood gas with  $\text{PaO}_2 \leq 70$  mm Hg, indicates severe disease, which is treated with steroids in addition to intravenous trimethoprim/sulfa, primaquin with either clindamycin or dapsone, or intravenous pentamidine. Trimetrexate plus dapsone may also be used. Prophylaxis with trimethoprim/sulfa or dapsone is a mainstay of AIDS treatment when CD4 counts are less than 200.

**Mycobacterium Avium Complex**

Mycobacterium avium complex (MAC), an atypical mycobacterial infection, is one of the most common opportunistic infections in AIDS patients in the United States, with an incidence of 18% to 43% in untreated patients (84–86). It may be present as a nonpathogenic colonizer or may cause disease in the bone marrow, lungs, liver, colon and rarely, the CNS. It occurs late in the course of the disease and may be indolent, with fevers, night sweats, weight loss and wasting, cough, diarrhea, abdominal pains, lymphadenopathy, and lymph node pain.

Effective drug combinations for treatment of MAC include clarithromycin, with ethambutol as an alternative. Rifabutin, clofazamine, ethambutol, and ciprofloxacin azithromycin and aminoglycosides (amikacin) have also been used (87). Clarithromycin has been shown to be effective in preventing disseminated MAC (88). Primary prophylaxis against MAC with azithromycin is recommended for those with CD4 counts less than 50 to 75 cells/ $\mu\text{L}$  (89).

**Gastrointestinal and Swallowing Disorders**

Gastrointestinal disease in AIDS is common and presents with diarrhea, weight loss, biliary disorders, abdominal pain, dysphagia, and oral disease (90–93). A wide range of causes including cytomegalovirus (CMV), herpes simplex virus (HSV), MAC, intestinal parasites, and malignancies such as KS and non-Hodgkin's lymphoma are seen. Drug reactions are also a frequent cause. Dysphagia is most often caused by *Candida albicans*, HSV, or CMV esophagitis. Other causes include hairy leukoplakia, KS, human papilloma virus infection, and neurogenic causes. The Sicca syndrome, seen often in association with lymphadenopathy, may be treated symptomatically with increased fluids, artificial tears, and careful attention to oral hygiene. Colitis often presents with abdominal pain and bloody or mucous diarrhea and is most often

caused by CMV, which responds to treatment with ganciclovir (94). *Clostridium difficile*, *Campylobacter jejuni*, *Entamoeba histolytica*, and *Shigella flexneri* are also seen in colitis in AIDS patients.

**HIV-Related Liver Disease**

Over the past several years, liver disease has risen to prominence in HIV patients. Many ARTs are hepatotoxic and a high percentage of HIV patients are also infected with hepatitis B, C, or both. Moreover, a higher percentage of HIV patients develop chronic infections that may progress more rapidly to cirrhosis than would otherwise be expected. Treatment for hepatitis C with pegylated interferon and ribavirin is commonly used in HIV patients and hepatitis B can be treated with the RT inhibitors lamivudine or emtricitabine, and tenofovir (79,95–100).

**Candidiasis**

Oral candidiasis (thrush) occurs in 43% to 93% of AIDS patients (101). It most often appears as creamy white, yellow or erythematous patches on the palate, tongue, and buccal mucosa and causes angular cheilitis and fissures at the corners of the mouth. With more severe immunodeficiency, candida may extend into the pharynx and esophagus. It presents more often in patients with CD4 counts less than 200 cells/ $\mu\text{L}$ , but can occur at higher counts as well. Candidiasis may be treated with oral nystatin suspension, clotrimazole troche, fluconazole or other azoles, or echinocandins.

**Kaposi's Sarcoma**

KS is a highly vascular malignant lesion containing endothelial cells and spindle-shaped mesenchymal cells and is associated with HHV8 coinfection. It can involve skin, oral mucosa, and visceral organs and often appears as dark blue or purple papules or nodules. Cosmetically, lesions can be treated by laser bleaching and spot radiation. Often, KS will regress with immune reconstitution on ART (102). More severe disease has been treated with antiretrovirals and drugs such as foscarnet (103), localized radiation, immunotherapy with interferon alpha, cytotoxic chemotherapy, and liposomal doxorubicin (104,105). Intralesional human chorionic gonadotropin (hCG) has also been effective (106). Associated edema may be controlled with the use of compressive garments, and painful lesions in the feet may be managed with the use of soft insoles and by unweighting the affected extremity.

**Intestinal Parasites**

*Cryptosporidium parvum* is an intracellular protozoan usually seen with CD4 counts below 200. It is responsible for about 1% of AIDS deaths (107). Oral paromomycin or azithromycin may be effective in decreasing diarrhea and stabilizing body weight (108). Microsporidiosis causes similar symptoms and may be treated with albendazole (109). Other intestinal parasites include *isospora belli*, *E. histolytica*, and *giardia lamblia* (110,111).

TABLE 47.3 Common Functional Impairment Syndromes in HIV

Cause of Impairment	When Seen	Features	Prognosis	Management
<i>Respiratory compromise and disseminated infection</i>				
Pathogenic fungi	Pre-AIDS and AIDS	Wasting, fevers, etc.	Benign or fulminate	Antifungal agents
mTB	Early AIDS	Nonspecific fever, cough, etc.	Fair, good with ART	Antituberculin therapy
PCP	Throughout AIDS	Nonspecific fever, cough, etc.	Good except in late AIDS	TMPX, dapsone, pentamidine; prophylaxis in all AIDS
MAC	Late AIDS	Fever, night sweats, weight loss, etc.	Poor but better with ART	Clarithromycin, ethambutol etc.; combination therapy. prophylaxis when CD4 count is <50–75
<i>GI and swallowing disorders</i>				
Neurogenic swallowing disorders	Throughout AIDS, especially late	Related to underlying neurologic disorder	Related to underlying disorder	Video fluoroscopy, modified swallow, parenteral nutrition
Sicca syndrome		Impaired lacrimation and salivation	Benign course	Symptomatic treatment (artificial tears, oral lubricants, etc.)
Candidiasis	Pre-AIDS and AIDS	Oral plaques, dysphagia	Good with treatment	Topical antifungal agents; systemic agents in severe cases
Kaposi's sarcoma	Throughout AIDS	Characteristic lesions	Slow progression	Appropriate chemotherapy
Intestinal parasites	Late AIDS	Diarrhea	Good if diagnosed	Antiparasitic agents
Weakness and fatigue				
Chronic fatigue	Pre-AIDS and AIDS	Many causes	Fair	Energy conservation and pacing
Fibromyalgia	Any stage of HIV	Pain and fatigue	Good	Standard measures (NSAIDs, etc.)
Myopathy (polymyositis)	Any stage of HIV	Proximal weakness	Good	Steroids, exercise as tolerated
AIDS wasting syndrome	Late AIDS	Proximal weakness	Poor	Supportive care, anabolic steroids, human growth hormone
<i>Pain syndromes and neuropathies</i>				
Arthritis and arthralgias		Psoriasis associated, Reiter's syndrome, reactive and HIV	Similar to idiopathic varieties	Similar to idiopathic varieties (NSAIDs, injections, joint preservation, etc.)
Distal symmetric neuropathy	Increased with decreased CD4 count	Distal numbness, pain, and decreased strength	Responds to symptomatic therapy	Tricyclics, neuroleptics, heat/cold, gait aids, orthotics
Segmental neuropathies	Early or late	Zoster, mononeuritis simplex/multiplex, vasculitis, etc.	Variable	Similar to that in non-HIV patients
Drug-induced neuropathies, vitamin deficiencies	Related to drugs	Didanosine, zalcitabine, stavudine, vincristine, dapsone, rifampin, isoniazide, ethambutol	Good	Cessation or alterations of medications, vitamin supplementation, symptomatic management
Plantar KS	Throughout AIDS	Characteristic lesions	Good	Radiation, custom insoles, etc.
Cognitive dysfunction				
HIV dementia	Late AIDS, but occasionally seen at presentation	Decreased memory, dysphagia, associated myelopathy	Poor	Antiretrovirals, memory book, adaptive strategies, decreased stimulation, etc.
Cryptococcal meningitis	Throughout AIDS	Fever, headache, meningismus, etc.	About 50% respond to treatment	Amphotericin B, followed by lifetime fluconazole

Neurosyphilis	Throughout AIDS	Nonspecific CNS	Fair, frequent relapse	High-dose PCN
Encephalitis (herpesviruses)	Throughout AIDS	Headache, seizure, altered consciousness, focal signs	May be self-limited, fair to good with antiviral treatment	Acyclovir for HSV, ganciclovir or foscarnet for CMV
Focal lesions (see below)	Throughout AIDS	Focal signs	Lesion specific	See below
Metabolic/iatrogenic dementia	Throughout HIV	Nonspecific CNS	Good	Proper diagnosis and correction of underlying problem
Focal brain disorders				
Cerebral toxoplasmosis	Throughout AIDS	Focal signs, altered consciousness, ring-enhancing lesions	Good with treatment	Pyrimethamine and folinic acid, plus sulfadiazine or clindamycin; prophylaxis when CD4 count is <100
PML	Advanced AIDS	Focal signs, altered consciousness	Very poor except in rare cases	Antiretrovirals
Primary CNS lymphoma	Advanced AIDS	Similar to above, occasional paraneoplastic signs	Extremely poor	Palliative radiation extends both quality and quantity of life
Other metastatic disease	Throughout AIDS	Similar to above	Lesion specific	Appropriate to lesion
CNS abscesses	Throughout AIDS	Similar to above	Lesion specific	Drainage of abscess, antimicrobials, antituberculin agents
CMV retinitis	Advanced AIDS	Visual field loss	Progressive	Ganciclovir and foscarnet
<i>Radiculopathies and myelopathies</i>				
Inflammatory	Early in HIV	Guillain-Barré, CIDP may be associated with nucleoside analogues	Very good	Same as in idiopathic forms
demyelinating				
polymyopathies				
CMV polyradiculopathy	Late AIDS	Flaccid paralysis	Arrested if treatment started quickly	Ganciclovir, foscarnet, rehabilitative interventions as in SCI
Vacuolar myelopathy	Late AIDS	Progressive paraparesis	Poor for recovery	As in other forms of SCI
Other myelitis	Throughout AIDS	Tropical spastic paraparesis (HTLV-1), herpesviruses, meningitis, Pott's disease	Poor	As in other forms of SCI
<i>Pediatric HIV</i>				
LIP	Common throughout AIDS	Nonspecific with variable course	Usually benign	Corticosteroids, symptomatic management for exacerbations
HIV encephalopathy	Common and progressive with AIDS	Static, progressive or progressive/plateau	Variable	Rehabilitative Interventions similar to spastic diplegic CP

AIDS, acquired immunodeficiency syndrome; CIDP, chronic inflammatory demyelinating polyneuropathy; CMV, cytomegalovirus; CNS, central nervous system; HIV, human immunodeficiency virus; HSV, herpes simplex virus; HTLV, human T-cell lymphotropic virus; LIP, lymphoid interstitial pneumonitis; MAC, *Mycobacterium avium* complex; mTB, *Mycobacterium tuberculosis*; NSAIDS, nonsteroidal anti-inflammatory drugs; PCN, penicillin; PCP, *Pneumocystis jirovecii* pneumonia; PML, primary multifocal leukoencephalopathy; SCI, spinal cord injury; TMPX, trimethoprim/sulfamethoxazole.

### Weakness and Fatigue in HIV

Persons with HIV are often fatigued for a variety of reasons, including fibromyalgia, pulmonary dysfunction, anemia, encephalopathy, endocrine dysfunction, myopathies, cardiomyopathy, psychiatric disorders, and depression. Fibromyalgia is commonly seen, and the response to traditional measures is generally good. Fatigue may also result from the effects of ART. The importance of preventative measures cannot be overemphasized with this population, including the use of light exercise to tolerance, early mobilization after an acute illness, and other measures to prevent common complications of immobility. Psychostimulants and anabolic steroids may also play a role (2,112–129).

### HIV-Related Cardiovascular Disease

Large cohort studies have demonstrated an increased risk of cardiovascular disease in HIV patients that is independent of other risk factors. This is manifest in increased rates of myocardial infarction and CVA in patients that may be related in part to chronic inflammation caused by HIV. Lipid abnormalities caused by some of the antiretroviral agents may also play a role (130).

Although the mechanisms involved are not clear, HIV-related cardiomyopathy is common (131). Other causes of cardiac dysfunction include pericardial disease, infectious and noninfectious endocarditis, metastatic KS, and lymphoma. When symptomatic, management is similar to that of congestive heart failure of other causes, with the use of vasodilators and diuretics. Exercise is instituted as tolerated in a similar fashion.

Chronic HIV infection and a number of the antiretroviral agents can also result in fat redistributions that can cause cosmetic, psychologic, and physical disability. Lypodystrophy appears as a combination of lypohypertrophy with abdominal, visceral adipose accumulation, dorsal cervical fat pad formation and gynecomastia and lipoatrophy with loss of subcutaneous fat from the extremities and face. Development of lypodystrophy is associated with increased rates of depression, nonadherence to medications, and metabolic syndrome (132,133).

### HIV-Related Metabolic Abnormalities

Some of the antiretroviral agents cause a decrease in insulin sensitivity that in turn may lead to increased rates of diabetes and metabolic syndrome (98–100,133).

Both HIV and some of the antiretroviral agents seem to lead to increased rates of osteopenia and osteoporosis in HIV infected individuals. This can lead to disability from pain syndromes and fractures (134).

An HIV-related nephropathy has been described (135). It is characterized by fluid and electrolyte abnormalities, acid-base imbalance, and proteinuria. Acute renal failure is usually the result of hypovolemia and ischemia or iatrogenic factors from the toxic effects of diagnostic agents and medications.

### Myopathies

HIV myopathy may present at any stage of infection, usually as proximal muscle weakness most prominently in the thighs,

particularly after exertion (136–138). Myalgia occurs in 25% to 50% of cases (139). Weight loss is common. Creatinine kinase is usually elevated, and EMG demonstrates abundant spontaneous activity with short-duration, low-amplitude polyphasic motor unit action potentials (140). Confirmation can usually be obtained from muscle biopsy, which demonstrates focal necrosis with regeneration. Prednisone has been reported to improve strength (141). The role of exercise is thought to be similar to that in non-HIV-associated myopathies.

Mitochondrial disease and associated myopathies are common in association with ART and may even persist in newborns whose mothers have undergone therapy for HIV (142–144). Nemaline myopathy has also been described and is clinically and electrophysiologically indistinguishable from HIV myopathy. Other myopathies may be toxic, autoimmune, or related to Coxsacki virus or human T-cell lymphotropic virus type I (HTLV-I) coinfection (145). These must be distinguished from the *AIDS-wasting syndrome*, which presents insidiously, late in the course of disease, with symmetrical proximal muscle weakness. Beneficial effects from anabolic steroids, growth hormone and, particularly, exercise, have been described (117,146–149).

### Pain Syndromes and Neuropathies

#### Arthritic Disorders

Arthralgias arising from a variety of ill-defined causes are common in association with HIV and with antiretroviral treatment (142,150). Arthritis is also relatively frequent, with psoriasis-associated arthritis, Reiter's syndrome, and reactive arthritis all being described (151–155). Septic arthritis, however, is a fairly rare complication of AIDS (156). The prognosis and management is comparable to that of idiopathic arthritides.

#### Avascular Necrosis

Numerous reports have surfaced in recent years of avascular necrosis (AVN) of the hips in patients with HIV (157–161). Early speculation that this is associated with the use of protease inhibitors has proven to be false (162). Some reports have demonstrated a positive correlation with steroid use (163,164). Of more concern is that radiologic evidence of AVN has been demonstrated in individuals with HIV who are asymptomatic for hip pain or dysfunction (165). It is not known how many of these if any will develop pain and impairment in mobility as a result of AVN; however, the potential for collapse of the femoral head must be considered. Presumably, those who are symptomatic can be managed similar to those with AVN from other causes.

#### Other Rheumatologic Disorders

Vasculitis is an unusual finding in HIV, with a reported incidence of 0.4% to 1% (166). Unfortunately, the prognosis is generally poor. Polyarteritis nodosa and an adult Kawasaki-like syndrome have also been described (167,168).

#### Distal Symmetric Neuropathy

Peripheral neuropathies are frequently seen in HIV, with a distal symmetrical polyneuropathy being demonstrable on EMG in 35% of AIDS cases (169–176). Symptomatic in about 18% of

patients with AIDS, its incidence increases with increasing viral load, and pathologic evidence can be found in nearly all cases on sural nerve biopsy or at autopsy. More common in adults, it has also been reported in children (177,178). It remains essential, however, to rule out treatable causes of neuropathy.

On biopsy, a “dying back” of distal fibers is seen, with loss of both myelinated and nonmyelinated fibers. In some cases, perivascular mononuclear inflammatory infiltrates are seen. Electromyographically, sensory nerve action potentials are reduced in amplitude initially and F waves are abnormal. In time, denervation potentials become evident in distal muscle groups and long-duration polyphasic motor unit action potentials, decreased recruitment, and increased amplitude may be seen (140,179).

The treatment of symptomatic peripheral neuropathies has included everything from traditional medications used in treating painful neuropathies to applied vibration and acupuncture (180–186).

### Other Sensorimotor Neuropathies

Drug-induced neuropathies commonly result from the antiretroviral drugs didanosine, zalcitabine, and stavudine. Other drugs commonly used in AIDS patients that can cause neuropathies include vincristine, dapsone, rifampin, isoniazide, and ethambutol (187–189). Mononeuropathy simplex and multiplex may occur early in HIV as a limited peripheral neuropathy that must be distinguished from segmental herpes zoster, also a common cause of painful neuropathy (190). A multifocal neuropathy associated with severe weakness and disability, and often with fever and cachexia, also may be seen in advanced AIDS. EMG is consistent with both axonal loss and demyelination (140). Motor neuron disease has rarely been reported in patients with HIV, and there is little direct evidence of an association between the two (191).

### Autonomic Neuropathy

Autonomic neuropathy is commonly found in association with HIV infection, particularly in advanced AIDS (192–196). Patients may experience orthostatic hypotension, syncope, impotence, decreased sweating, impaired gastric motility, and diarrhea. As always, it is important to rule out iatrogenic causes from the use of common medications.

## Cognitive Dysfunction in HIV

### HIV-associated Dementia

The most common cause of cognitive dysfunction is HIV-associated dementia, also known as the *AIDS dementia complex*, *subacute encephalitis*, and *HIV encephalopathy* (197–200). Although it is usually not seen until advanced disease, it may be present in 3% to 7% of cases at the time of diagnosis and will eventually be found in 15% to 20% of those with advanced disease, making it the leading cause of dementia in young adults (201). Ironically, the incidence in individuals undergoing ART with CD4 counts greater than 200 may actually be increasing (202). Although poorly understood, monocytes and dopaminergic pathways have been implicated (203–208). Alcohol and cocaine may play a role in hastening the progression of

dementia (209). Although electrophysiologic abnormalities can be demonstrated on evoked potential testing in a majority of individuals with HIV and abnormalities are evident in functional imaging studies (210), cognitive dysfunction does not usually become evident prior to the development of AIDS, and the existence of subtle cognitive changes in early disease remains controversial (211,212).

### Cryptococcal Meningitis

Cryptococcus is an important fungal pathogen in patients with CD4 counts under 200 cells/ $\mu$ L (213). The incidence has declined since the advent of ART (214). Infection most often presents with meningitis, and symptoms include fever, headache, neck stiffness, and memory loss. Patients may show signs of lethargy, confusion, meningismus, or cranial nerve palsies. Signs and symptoms in AIDS patients, however, are often mild (215). Cryptococcal antigen may be detected in the cerebral spinal fluid (CSF) or serum for diagnosis. Initial treatment is with amphotericin B or fluconazole followed by fluconazole maintenance (216–219). Prophylaxis with low-dose fluconazole may be of use in high-risk patients (220).

### Other Causes of Cognitive Dysfunction

*Treponema pallidum* may cause chronic meningitis, neuropathy, or dementia when infecting the CNS of AIDS patients (neurosyphilis) (221,222). CSF pleocytosis is often seen, and a CSF Venereal Disease Research Laboratory (VDRL) test may be positive, but sensitivity is low. Treatment is usually with intravenous penicillin G, but relapses are common.

Varicella zoster, a common cause of pneumonia and skin eruptions in AIDS patients, also results in a variety of neurologic syndromes, including painful nerve palsies, transverse myelitis, ascending myelitis, encephalitis, and leukoencephalopathy (223–225). In contrast to HSV encephalitis, herpes zoster encephalitis rarely causes focal neurological signs, deep alterations in consciousness, or seizures. The usual duration of neurologic symptoms is around 16 days, and the outcome is generally better than that with the other CNS infections. PCR assay for HZV may aid in diagnosis and management. Acute mononucleosis caused by Epstein-Barr virus is also common, often leading to encephalitis, acute cerebellar syndrome, transverse or ascending myelitis, or acute psychosis (226).

Other causes of cognitive dysfunction include CMV encephalitis, aseptic meningitis, and cerebral vasculitis (166,190,227–229). Cognitive dysfunction also may result from disorders that cause focal CNS syndromes. As always, with any dementia workup, it is essential to rule out iatrogenic and other potentially treatable causes.

### Focal Brain Lesions found in HIV

The focal deficits seen in association with AIDS are related directly to the areas of the brain affected and may include blindness, hemiparesis, ataxia, aphasia, dysarthria, and cranial nerve deficits (190,230–234). Movement disorders, including hemichorea-ballismus, segmental myoclonus, postural tremor, parkinsonism, and dystonia, also may be found.

### Toxoplasmosis

Cerebral toxoplasmosis is the most common CNS mass lesion in AIDS, occurring in 3% to 40% of cases (190,235–237). Without prophylaxis, 30% of previously toxoplasma-seropositive AIDS patients may relapse when the CD4 count drops below 50. Most patients present with focal or nonfocal neurologic signs produced by space-occupying lesions. Headaches, confusion, lethargy, and seizures are common. Contrast-enhanced head CT or magnetic resonance imaging (MRI) reveals single or multiple ring-enhancing lesions that may be distinguished from lymphoma by biopsy or radiolabeled thallium uptake (233,238–240).

A common diagnostic strategy is to initiate antitoxoplasma therapy and observe for clinical response, which is often dramatic. Treatment regimens include pyrimethamine and folinic acid plus either sulfadiazine or clindamycin. Patients with a positive antitoxoplasma immunoglobulin G antibody should take prophylaxis when their CD4 count is less than 100 cells/ $\mu$ L (241). Trimethoprim/sulfa, often used for PCP prophylaxis, is effective, as is clindamycin plus pyrimethamine.

### Progressive Multifocal Leukoencephalopathy

Progressive multifocal leukoencephalopathy (PML) is a white matter disease associated with infection by the JC virus (230). It occurs in approximately 4% of AIDS patients. Single or multifocal lesions confined to the white matter without the presence of a mass effect or contrast enhancement may be seen on MRI. Diagnosis can be made based on radiographic appearance or more definitively by biopsy (242). The median survival is of the order of 2 to 4 months, although in approximately 10% of cases a more benign course is seen, and spontaneous remissions may even occur after ART is added (243–245).

### CNS Lymphoma

CNS lymphoma is associated with late-stage AIDS and CD4 counts of less than 100 cells/ $\mu$ L. It may present as a mass lesion with confusion, headache, memory loss, or focal neurologic signs. Untreated, it usually progresses to death in 1 month or less. Palliative radiation can temporarily improve symptoms and extend survival, with an increased quality of life in 75% of cases (246). Associated paraneoplastic syndromes are common. Rarely, other malignancies and metastatic lesions may be seen in the brain, particularly from KS (247).

### CMV Retinopathy

CMV is one of the most common pathogens in AIDS patients, with more than 90% of patients showing evidence of past exposure and up to 40% of those with advanced disease developing active CMV disease (248). About 85% of CMV disease in AIDS patients presents as retinitis, which usually affects those with CD4 counts less than 50 cells/ $\mu$ L. Productive infection of the retina can cause full thickness necrosis, although patients may be asymptomatic and gradual visual loss may be unnoticed until vision is significantly impaired. Ophthalmologic examination shows characteristic perivascular yellow-white lesions that are frequently associated with

retinal hemorrhage (249). These must be distinguished from cotton wool spots, which are white, fluffy, superficial infarcts of the nerve fiber layer that usually spontaneously regress and do not lead to blindness.

The mainstay of treatment has typically involved a combination of ganciclovir, a nucleoside analogue, and foscarnet, a pyrophosphate analogue (249–251). Cidofovir, a newer agent with a long half-life, can suppress CMV up to 3 weeks after a single administration with probenacid (252,253). Intravitreal injection of ganciclovir and cidofovir as well as intraocular implants of timed-release devices with ganciclovir or foscarnet have also been used with success (254–256). Complications are common with all these drugs (see Table 47-2). Although the incidence is decreasing as a result of ART, those infected continue to have a poor prognosis, and drug resistance is common (250,251,257,258). Eventual progression to blindness can occur, making early institution of visual retraining and blind rehabilitation particularly important.

### Other Causes of Focal CNS Syndromes

HSV-I may infect the brain in AIDS patients, causing an encephalitis characterized by the acute onset of headache, behavioral changes with focal neurologic signs, seizures, and coma. Although an increased incidence of thromboembolic cerebrovascular events has been reported, it is not clear that the incidence is greater than that of the general population (259–262). This is in contrast to cerebral vasculitis, which does have an association with AIDS. Primary CNS angiitis is a rare and usually fatal disorder that has a predilection for small cortical vessels (229,263,264). Bacterial and fungal abscesses may also cause focal neurologic deficits (265). TB is of particular concern and may require biopsy for diagnosis. Antituberculin therapy is often initiated in those with a positive PPD (Purified Protein Derivative tuberculin test) and a new focal lesion when the diagnosis is uncertain (266).

### Radiculopathies and Myelopathies

#### Inflammatory Demyelinating Neuropathies

HIV is a major cause of inflammatory demyelinating polyneuropathies and must always be considered in the differential (187,267–269). Guillain-Barré syndrome, or acute inflammatory demyelinating polyneuropathy (AIDP), occurs early, often around the time of seroconversion, and is clinically and histopathologically indistinguishable from the idiopathic form. It is managed similarly. In some cases, chronic inflammatory demyelinating polyneuropathy (CIDP) or relapsing polyneuropathy may be seen.

Nerve conduction studies are significant for prolonged sensory and motor latencies with patchy slowing to less than 60% to 70% of normal (140). Marked reduction in motor action potential amplitude or even motor conduction block may be indicative of focal demyelination. F wave and H reflexes are often markedly delayed or absent. The EMG needle exam usually fails to show abnormal spontaneous activity, although denervation potentials with diminished recruitment may sometimes be seen in weak distal muscles.

### CMV Polyradiculopathy

CMV causes a common and debilitating peripheral neuropathy in which CMV infects the nerve roots and ganglia (268,270). Patients present with back and lower extremity sensory changes and weakness that may rapidly progress to flaccid paralysis (267,271). It can be rapidly fatal unless treatment is started within the first 24 to 48 hours (227,268,270). Treatment is effective in halting progression, although patients are often left with severe deficits that may require rehabilitation.

Findings include loss of lower extremity deep tendon reflexes, saddle anesthesia, and urinary retention, whereas upper extremity strength is preserved. Diffuse spontaneous activity is seen on EMG, with decreased recruitment but near-normal conduction velocities (140). The CSF often has a pleocytosis with neutrophils and may show elevated protein and inclusion cells that may stain positive for CMV antigens (227,267). Improvement upon treatment with ganciclovir has been described (174,267,272,273). Foscarnet also can be effective.

### Vacuolar Myelopathy

Vacuolar myelopathy is the most common cause of spinal cord dysfunction in HIV, being found in 11% to 22% of AIDS cases and demonstrable in up to 40% of cases at autopsy (190,274,275). It is strongly associated with HIV dementia and shares a virtually identical histopathology. Patients present with progressive paraparesis, ataxia, posterior column sensory loss, spasticity, and neurogenic bowel and bladder.

Spinal cord dysfunction may also result from viral myelitis secondary to varicella zoster virus, HSV, CMV, and HTLV-I (276). Spinal cord disorders may also be seen with tuberculin involvement (Pott's disease), multiple sclerosis, and aseptic, cryptococcal and lymphomatous meningitis (275,277).

## PEDIATRIC HIV

Pediatric cases of HIV differ significantly from their adult counterparts (278–280). More than 80% of cases of HIV infection in children are the result of perinatal transmission, with transmission from blood products being less frequent. The most effective strategy to minimize vertical transmission is prophylactic treatment of the mother as well as the newborn (39,281). Because of transplacental transmission of antibodies, however, most infants of HIV-positive mothers will initially be seropositive at birth, with signs of infection developing in approximately 80% of those with disease at a median age of 5 months. Significant advances in medical management over the past 5 years, however, have resulted in a substantial decrease in the progression to AIDS and an improvement in survival (282).

### Opportunistic Infections

In contrast to adults, opportunistic infections of the nervous system are extremely uncommon (283). AIDS-defining criteria in children include recurrent bacterial infections,

opportunistic infections, lymphoid interstitial pneumonitis (LIP), malignancies, cardiomyopathies, hepatitis, nephropathy, and encephalopathy. Infants with AIDS often present with hepatosplenomegaly, lymphadenopathy, diarrhea, oral candidiasis, parotid enlargement, delayed developmental milestones, and failure to thrive.

Over 80% of HIV-infected children eventually develop either acute or chronic lung diseases. While most are acute infectious processes, chronic diseases such as LIP may occur in 30% to 50% (284–286). The etiology and natural history of LIP are incompletely understood. Although some patients are asymptomatic with infiltrates on chest x-ray, others experience a slowly progressive course with exacerbations caused by lung infections, and some may progress to chronic respiratory decompensation and hypoxemia. HIV-infected children with LIP are believed to have a better long-term prognosis than those with other pulmonary infections. Corticosteroids are used to suppress the lymphocytic infiltrate.

### HIV Encephalopathy

The most common neurologic disorder seen in children is HIV encephalopathy (287–290). This may be static, progressive, or progressive with a plateau. Static encephalopathy is characterized by delayed acquisition of developmental skills and is seen in 25% of those with CNS deficits. With progressive encephalopathy, on the other hand, the pace of development becomes progressively slower and may halt altogether, or show signs of regression. The clinical picture is not unlike that of spastic diplegic cerebral palsy, but with progressive deficits.

Other children may demonstrate more subtle neurodevelopmental deficits, including easy fatigability, mild depression, expressive language deficits, and mild regression in school performance. The response to ARTs has been reported to be good. Uncommon neurologic disorders that may be encountered in children include CNS lymphoma, corticospinal tract degeneration, and, rarely, myelopathy, myopathy, and peripheral neuropathy (177).

With the advent of ART, many children born with HIV may live relatively normal lives, although this is not true in much of the developing world, where access to therapy remains limited (280,282,291–293). ART has been shown to reduce viral load in children just as in adults, and CNS pathology has been shown to be reversible with antiretroviral treatment as well. More importantly, neuropsychiatric indicators have been demonstrated to improve significantly with the institution of treatment. As of this writing, a number of children born with HIV are now into their teens; however, the long-term adverse effects of antiretroviral treatment will only become clear over time.

## PSYCHOSOCIAL AND VOCATIONAL ISSUES

HIV remains one of the most stigmatized diseases of our time. As in oncologic rehabilitation, patients may be faced with issues of death and dying but with appropriate therapy, hope, and long-term survival. Discrimination remains a particular

problem due to the infectious nature of the disease and to public misperceptions and prejudice. The health of the caregiver, if there is one, is of particular concern when developing rehabilitation strategies. As always, rehabilitation professionals must deal with the patient in the context of their surroundings and their external support network.

Before the onset of symptoms, 70% to 90% of people with HIV are still employed (294). Even in the first year after the onset of symptoms, fewer than one-third leave the workforce. People with HIV commonly experience workplace discrimination and, with advancing symptoms, may experience a diminished work capacity. Significant controversy exists regarding persons with HIV in the health care field. Those who are forced to leave the workforce face a potential loss of health insurance. In all other respects, vocational rehabilitation of the HIV patient is similar to that of the patient with cancer or multiple sclerosis, but always keeping in mind the potential for full recovery and long-term health (295,296).

## THE FUTURE OF HIV REHABILITATION

The management of HIV is one of the most rapidly changing fields of medicine, with entirely new treatment strategies often becoming available in a period of months rather than years. By the time this is published, it is likely that new medications not discussed here will be in common usage. The complexion of HIV rehabilitation continues to evolve rapidly, and the future of HIV rehabilitation is thus largely unknown. As a cure still does not seem to be imminent; however, it is reasonable to expect a need for rehabilitation interventions for the foreseeable future.

Most HIV strategists currently view HIV as being managed as a chronic disease similar to diabetes mellitus. Although not curable, its progression will be held in check by medical therapies. This comparison to diabetes may be particularly apt in the case of rehabilitation. Although the most serious morbidity and mortality of diabetes is avoidable, even with stringent control of blood glucose, amputation, blindness, and peripheral neuropathy remain common sequelae that often respond to rehabilitation interventions. While new HIV treatments are indeed remarkable in their ability to arrest development of functional impairments and disability, they introduce toxicities of their own that may lead to yet a new set of impairments.

It has now become apparent that long-term viral suppression with antiretrovirals is achievable for most HIV patients, but that it requires an incredible 95% adherence to treatment regimens (297). Missed doses may allow viral replication to produce drug-resistant strains. Much of the effort in care for patients is expended in encouraging and enabling this high-level adherence. Adherence is an integral part of HIV treatment programs.

In the last edition of this chapter, we speculated that rehabilitation professionals might face a future practice consisting of otherwise healthy individuals with HIV and a variety of disabling conditions such as Guillain-Barré syndrome, polymyositis, distal symmetric polyneuropathy, HIV dementia, and vacuolar

myelopathy. Although the numbers remain limited, many have in fact noted an increase in potentially disabling conditions in otherwise healthy individuals with HIV, leading some to call for more emphasis on rehabilitation (3,298–301). Remarkably, exercise has been shown to play a significant role in improving not only the aerobic capacity but also immune system function in individuals with HIV (302–307). The role of rehabilitation may thus be critical not only in keeping these people functional in their communities, but in maintaining their health as well.

PART

# IV

## **Secondary Conditions and Complications**

# Physical Inactivity: Physiological and Functional Impairments and Their Treatment

While physical activity and exercise are generally well-accepted concepts in healthy persons, the consequences of inactivity and bed rest are less well understood by clinicians and the general public. The deleterious effects of immobility and physical inactivity are common and may affect multiple body systems and the stealthy onset of these effects may minimize the awareness of the dangers and the timely response for prevention and treatment.

Bed rest and immobilization were widely used before 1950 in the management of trauma and acute and chronic illness, before the physiologic effects were well understood. It was generally assumed that rest fostered healing of the affected part of the body. What was not appreciated was that immobility and inactivity could be harmful to the unaffected parts of the body. For example, the immobilization of long bones with a rigid cast has a beneficial effect on bone healing after fractures. However, it may also result in undesirable effects, such as joint contracture and atrophy of the healthy muscles and bones.

Clinical studies on enforced bed rest in normal subjects and on astronauts in microgravity conditions (in which their bodies rest from the effects of gravity) have shown significant undesirable effects that may override the therapeutic effects of bed rest in subacute and chronic conditions, impacting complexity and cost of medical treatment as well as functional outcome.

A review of randomized controlled trials on the effects of bed rest and immobility did not demonstrate improvement or better outcome of primary medical conditions for those on extended periods of bed rest. In many cases, worsening occurred if early mobilization was not provided (1). Persons who are chronically sick, aged, or disabled are particularly susceptible to the adverse effects of immobility. A patient with motor neuron disease and its accompanying limb weakness or spasticity would be expected to develop the same musculoskeletal complications but at a much accelerated rate. The healthy subject on prolonged bed rest may only show some degree of atrophy and weakness; the neurologically impaired subject will likely also lose a significant amount of independent functioning. Many of these complications could be easily prevented or,

if they occur, easily treated once they are recognized. Therefore, the prevention of such complications should be one of the basic principles of any rehabilitation management plan.

Negative effects of immobility or inactivity are rarely confined to only one body system (Table 48-1). Immobility reduces the functional reserve of the musculoskeletal system, resulting in weakness, atrophy, and poor endurance. Metabolic activity and oxygen utilization in the muscle are reduced, degrading the functional capacity of the cardiovascular system as well (Fig. 48-1). In addition, postural hypotension and deep venous thrombosis (DVT) are commonly encountered in bedridden patients. Immobilization osteoporosis is yet another complication that has been well documented in the studies of astronauts and individuals exposed to prolonged bed rest. Over time, clinical experience has dictated a move toward earlier mobilization and provision of functional training with a resulting decrease in the length of hospitalization and in the incidence of major morbidity associated with prolonged inactivity (2).

The most deleterious effects of inactivity can be grouped together under the general term “deconditioning,” which is defined as reduced functional capacity of musculoskeletal and other body systems. It should be considered a distinct diagnosis from the original condition that has led to a curtailment of normal physical functions (3). This chapter describes the widespread effects of immobility and physical inactivity, reviews the evidence-based therapeutic and prophylactic approaches to counteract these complications, and redirects attention to the benefits of physical activity and exercises in maintaining a good health and independence.

## MUSCULOSKELETAL EFFECTS OF IMMOBILITY AND INACTIVITY

Moving the body and limbs freely in the environment is a principal physical function requiring that the muscles, nerves, bones, and joints be in an optimal physiologic state. Disuse weakness and reduction of free joint motion can initially cause minimal functional limitations that can be easily overlooked or

**TABLE 48.1** Adverse Effects of Immobility and Inactivity

System(s)	Effect(s)
Musculoskeletal	Muscle weakness, fatigue, and atrophy Muscle and joint contractures Muscle stiffness and pain Osteoporosis Hypercalcemia
Cardiovascular and pulmonary	Redistribution of body fluids Dehydration Orthostatic intolerance Reduction of cardiopulmonary capacity Reduction of $VO_{2max}$ Elimination of bronchial secretions Hypostatic pneumonia
Genitourinary and gastrointestinal	Urinary stasis, stones, and urinary infections Loss of appetite Constipation
Metabolic and endocrine	Glucose intolerance Electrolyte alterations Increased parathyroid hormone production Other hormone alterations
Immune system	Impaired wound healing Reduction in cellular immunity Resistance to infection reduced Anti-inflammatory suppression reduced
Cognitive and behavioral	Sensory deprivation Confusion and disorientation Anxiety and depression, memory Decrease in intellectual capacity Impaired balance and coordination
Cellular/Genetic	Diminished gene expression Mitochondrial dysfunction

neglected. However, advanced contractures and disuse weakness can cause a loss of mobility and decrease in activities of daily living (ADL) functions (4).

For the neurologically impaired or multiple trauma victim, considerations such as preserving functional range of

**FIGURE 48-1.** Inactivity, immobility, and prolonged bed rest influence total body functioning.

motion (ROM) may seem trivial; however, neglect of these simple factors can be responsible for prolonging hospital stays, increasing the use of health care resources, and prolonging dependency in mobility and ADL (5).

Three main types of adverse effects from inactivity are encountered in the musculoskeletal system: muscle atrophy and weakness, joint contracture, and immobilization osteoporosis (see Table 48-1).

## INACTIVITY OF SKELETAL MUSCLE

### Physiological Impairments

#### Disuse Atrophy

Decrease in the size of muscle fibers and reduction of muscle mass are the hallmark of muscle atrophy. In a lower motor neuron lesion, the atrophy is regional and related to the particular nerve or root. Atrophy associated with muscle disease is more pronounced in the proximal muscles. The atrophy of disuse is generalized or localized to the immobilized limb(s) and more prominent in the antigravity muscles. It is a consequence of the limited physical activity and musculoskeletal loading that occurs during immobilization, immobility, bed rest, or exposure to microgravity during space flight. As a general rule, increased muscular activity leads to hypertrophy, whereas limited physical activity leads to disuse atrophy and weakness. The changes in muscle fiber size either in atrophy or in hypertrophy and phenotype changes of muscle fibers are the results of remarkable muscle plasticity and adaptability to external physical demands to generate adequate or peak contraction and endurance.

Disuse atrophy is defined as an alteration of metabolism and muscle cell homeostasis in response to muscle inactivity. Recent studies indicate that muscle protein synthesis as well as whole body protein production is significantly reduced during immobility and is considered the main contributor to muscle atrophy. The rate of muscle wasting during bed rest is slow during the first 2 days but becomes rapid thereafter. By 10 days, it reaches 50% of eventual muscle weight loss. Similarly, muscle protein synthesis is reduced to 50% of the baseline level at 14 days of immobilization and then gradually tapers off to reach a new steady state (6). Reeves et al. (7) studied skeletal muscle changes in healthy men exposed to microgravity condition and found a decrease in calf muscle volume by 29%, resting fascicle length of medial head of gastrocnemius and their pennation angulation by 10% and 13%, respectively, and physiological cross-sectional area (PCSA) by 22%. In disuse atrophy, especially if muscle is immobilized in a shortened position, that is flexion, the number of sarcomeres in series is reduced as a result of diminished chronic stretch and adaptation of the muscle to a new resting length. By contrast, immobilization in an elongated muscle resting position or during musculoskeletal growth increases the number of sarcomeres in series (8). In addition, the number of sarcomeres in parallel is reduced contributing to the reduction of muscle fiber PCSA (muscle volume/fascicle length) (9). From data obtained on the

PCSA, the reduction in the number of sarcomeres in parallel is twofold greater than reduction of sarcomeres in series. This indicates that reduction of isometric strength is in proportion to the loss of total number of sarcomeres in parallel and that they are more affected by disuse (9).

Disuse atrophy of type I and type IIa muscle fibers is more prominent than type IIb fiber atrophy during immobility. The mean size of type I fibers in human soleus muscle is decreased by 12% and 39% at 2 and 4 months of bed rest, respectively. This reduction could be prevented by simulating gravity loading for 10 hours a day in supine position (10). Individual muscle thickness can be clinically measured *in vivo* for some muscle by ultrasound scanning. Using this technique, the reduction of muscle thickness after 20-day bed rest is on average -2.1% to -4.4% and varies significantly for different muscles of the lower limbs (11). Magnetic resonance imaging (MRI) studies have, however, revealed much greater percentages of atrophy of the muscles in the lower limbs with the same duration of bed rest (12). Furthermore, consecutive MRI studies of thigh and calf muscles revealed that cross-sectional area and muscle volume of the gastrocnemius and soleus muscles were reduced to a greater extent than knee extensors and flexors (-9.4% to -10.3% vs. -5.1% to -8.0%) after 20 days of bed rest (12). However, using specific tests, the mean cross-sectional area reduction for the dark adenosine triphosphatase (ATPase) and light ATPase fibers is 46% and 69%, respectively, after 20 days of immobility (13).

Along with muscle fiber atrophy, the synthesis of collagen fibers is also reduced, although this reduction is much less than the reduction in synthesis of muscle proteins. This leads to a relative increase of muscle collagen content and changes in its mechanical elastic properties. The increase in muscle stiffness and alteration in viscoelastic properties of plantar flexors during space flight correlated with the duration of the flight, but the changes were less prominent than during bed rest (14). In both situations, weight bearing is limited, but joint motion is free and abundant during space flights. In healthy subjects with normal mobility, the main resistance to excessive elongation of muscle fiber is due to resistance of the myofibrils and in a lesser part to the sarcolemma itself. Titin, a myofibrillar protein, appears to have a major role in providing resistance to passive elongation, and it is increased in immobility. When titin is chemically removed, this resistance to passive stretch is significantly diminished (14).

Prominent histochemical changes also occur in muscle during bed rest and immobility. Serum creatine kinase (CK) isomer and fibroblast growth factor release (after myofiber injury) are both reduced during bed rest, and this is proportional to the reduction in muscle fiber size. Resistance exercises during bed rest significantly increase the level of these factors and prevent muscle fiber atrophy, indicating that myofiber wound-mediated fibroblast growth factor may play an important role in disuse atrophy (15). Myostatin is a growth factor-beta protein that inhibits muscle synthesis and is increased during bed rest. After 25 days of bed rest, the total lean body mass declines by an average of 2.2 kg, and plasma myostatin-immunoreactive protein level increases by 12%. It is

speculated that suppression of myostatin may prevent muscle atrophy during space flight (16).

The muscle mass loss associated with aging is called sarcopenia. It is a major cause of disability and frailty in the elderly population. Inactivity is one of the many factors responsible for development of sarcopenia, along with decline in number of alpha-motor neurons, reduction in growth hormone, inadequate protein intake, and chronic overproduction of catabolic cytokines. High-intensity resistance exercise can reverse sarcopenia, indicating that physical inactivity is a major risk factor for weakness in elders (17). Many articles have been written about functional decline in hospitalized and nursing-home patients. General deconditioning in elderly persons is a frequent cause of functional decline, falls, and increased dependency. Reconditioning takes much longer in the elderly than in younger persons.

Although the primary reason for atrophy is reduction of muscle protein synthesis, an increased protein breakdown with nitrogen loss is also found during immobility despite the fact that the major energy sources during bed rest are primarily derived from carbohydrates and fat. It is believed that decline of mitochondrial function and the reduction of protein synthesis are the main reasons for the onset and progression of disuse atrophy. However, in the later stages of disuse muscle atrophy, the process of protein degradation may become more prominent than decrease in protein synthesis. This may be aggravated by gastrointestinal mechanisms, such as loss of appetite and reduced intestinal absorption of protein. Although daily loss of nitrogen for an immobilized healthy person may reach 2 g/day, a nutritionally depleted person may lose as much as 12 g/day. Urinary excretion of creatine is minimal under normal conditions, except in pregnancy and infancy. The excretion of creatine is much greater in starvation, diabetes, muscular dystrophy, hyperthyroidism, and fever, as well as during immobility. Prolonged bed rest and weightlessness causes a significant increase in the excretion of both creatine and creatinine, the mechanism which is not well understood (18).

### Loss of Strength

Muscle weakness, reduced endurance, and tolerance to work are the functional consequences of muscle atrophy. The maximal strength of a muscle can fall to 25% to 40% of baseline level when a person is exposed to minimal exertions over a 2- or 3-week period (19). During strict bed rest, muscles may lose 10% to 15% of their original strength per week and, over 4 weeks, 35% to 50%. The loss of strength is rapid after the first day of immobilization and reaches its maximum 10 to 14 days later (20). Resistance leg exercises performed above 50% of maximum every second day, for 20 minutes by healthy subjects on bed rest, can maintain the muscle protein synthesis at the same level as healthy subjects engaged in normal physical activity (21). A study on dynamic leg press training during bed rest demonstrated preservation of baseline cross-sectional area and strength for the knee extensors and flexors but not for ankle plantar flexors and ankle dorsiflexors. This can adversely affect functional locomotion, as ankle plantar flexion contributes to forward propulsion (22).

The loss of strength associated with disuse atrophy is more prominent in the lower limbs than in the upper limbs. Loss of muscle power during immobilization reaches -20% to -44% in knee flexors and extensors, comparing to an insignificant loss in the upper limbs of -5%. The decrease in peak muscle tension of knee flexors and extensor ranges from -19% to -26%, far more than the reduction in cross-sectional area of these muscles (-7%), indicating that loss of strength and power is proportionally greater than reduction in size of the respective muscles (23). The major contributors to the loss of strength and endurance in persons with disuse atrophy are the reduced number of myofibrils per fiber volume, reduction in size and number of mitochondria, muscle fiber nuclei, and reduction of sarcomeres in parallel (10).

Another aspect of disuse weakness is reduction of maximal instantaneous muscular power. It can be reduced to a greater extent than the peak muscle strength of one repetition maximum in bed rest subjects. The loss of strength has been well documented in immobility; however, the loss of explosive muscle power as measured by the maximal jump with both feet on force plate was only recently studied. After 45 days of bed rest, instantaneous muscular power was reduced 24%, and recovery required one and half months of remobilization (24). These findings indicate that specific training for instantaneous power should be considered during space flight or prolonged bed rest to preserve functions such as standing up, climbing, and performing transfer functions.

Decline in muscle twitch and tetanic tension parallels the decline in muscle strength. In rats, maximal tension obtained by electrical stimulation in the soleus muscle declined significantly after 6 weeks of immobilization (25). Changes in contractile forces of immobilized muscle are the result of diminished levels of myofibrillar proteins and also due to a reduction of sarcoplasmic reticulum calcium ion uptake, but not the rate of its release (26).

### Loss of Endurance

Multiple studies have demonstrated that prolonged inactivity causes a significant and progressive reduction in muscle endurance. Unexercised muscle demonstrates a reduction of adenosine triphosphate (ATP) and glycogen storage sites and rapid depletion of them after resumption of activity. Reduction of muscle protein synthesis and oxidative enzyme function, and premature anaerobic energy production with rapid accumulation of lactic acid, are important factors leading to fatigability and reduced endurance (27).

Metabolic and enzymatic alterations in unexercised muscle result from reduced demand for oxygen and reduction in the blood supply. Initially after bed rest, succinate dehydrogenase enzyme activity per muscle fiber increases, but later, the overall amount is reduced (28). Oxidative enzyme activity and content as well as the number and size of mitochondria are all reduced during immobility (29). Unexercised muscle also shows a decreased ability to utilize fatty acids when compared with trained subjects.

Ferretti et al. studied peripheral and central factors that contribute to the decline of  $\text{VO}_{2\text{max}}$  after 42 days of bed rest.  $\text{VO}_{2\text{max}}$  was found reduced by 16%, cardiac output by 30%, and oxygen delivery by 40%, which parallels the reduction in muscle cross-sectional area of 17%, volume density of

mitochondria by 16%, and total mitochondria volume in the magnitude of 28%. Oxidative enzyme activity falls by 11%. These decrements indicate a significant contribution of both peripheral and central factors in causing the decline in  $\text{VO}_{2\text{max}}$  after immobility, confirming a close interrelationship between the muscular and the cardiovascular system (27).

The following sequence of events transpires in the deconditioning process. Prolonged reduction of muscle repetitive contractions below 50% of maximum alters muscle protein synthesis and decreases glycogen and ATP storage, causing a reduction of oxidative enzymes, mitochondrial function, and microvascular circulation, impacting muscle metabolic activity. As a result, the oxygen supply is attenuated, and the extraction of oxygen from blood is diminished, further negatively affecting  $\text{VO}_{2\text{max}}$  and cardiovascular reserve. The loss of muscle mass leads to reduction of muscle strength and endurance, reducing muscle blood flow, red blood cell delivery, oxidative enzyme activity, and oxygen utilization in the muscle precipitating a further loss of musculoskeletal and cardiovascular functional reserve to low or dangerous levels. In this cascade of events, specific muscle gene activation and expression are altered as well. Physical inactivity causes change in muscle fiber type composition and decreases formation of oxidative muscle fiber types I and IIa, the main factors in reduction of endurance and fitness (30).

### Functional Impairments of Disused Muscle Mobility and ADL

The progressive weakness and reduced stamina resulting from inactivity negatively impact the ability to perform basic mobility and ADLs. In the lower limbs, type I muscle fibers, which are active during standing and slow ambulation, are especially affected with a rapid reduction in endurance. If the quadriceps muscle is immobilized in an extended position, the deep layer of vastus intermedius, which has predominantly type I and type IIa fibers, shows the greatest histochemical changes in contrast to the rest of the muscle (31). Such accelerated rate of atrophy and weakness was also noted in hip and back extensors, hip abductors, and ankle plantar flexors and dorsiflexors, impacting the ability to walk (5). Disuse weakness and loss of endurance will result in impaired ability to perform ADLs and ambulate safely, reducing personal independence (Fig. 48-2).

### Muscle Pain and Stiffness

Patients frequently complain of back pain during bed rest. The cause of this pain is still not fully understood. Recent studies in which spine length and degree of movement were measured by miniature ultrasound transmitters have demonstrated that back pain is more prominent when trunk movements are limited in a supine position. It is speculated that localized, prolonged, low-intensity isometric muscle contractions may cause this pain. Back pain can be averted by stretching exercises and walking (32).

Limb muscle pain and stiffness occur after generalized immobility or focal limb immobilization, especially in the presence of limb swelling. However, gentle static or intermittent stretching can alleviate this problem and prevent the reduction in number of sarcomeres in series (33). It has been shown that the position in which a joint is immobilized has a significant

**FIGURE 48-2.** A sequence of contracture development occurred from hip down to knee in a patient with traumatic hip fracture treated operatively with the pins. As a result of hip-flexion contracture and immobility, the hamstring and eventually posterior capsule with neurovascular soft tissue of the knee became tight and contracted, causing knee-flexion contracture. With these contractures, a person must walk on the toes, which increases energy expenditure.

influence on the number of sarcomeres present in a single muscle fiber (33). When immobilized in a shortened position (extensors in a fully extended position or flexors in a fully flexed position), a muscle can lose 40% of its original number of sarcomeres, contributing significantly to weakness and muscle stiffness (34).

### Disuse Weakness, Deconditioning, and Cardiovascular Disease

A lack of adequate muscle activity adversely affects the cardiovascular and related systems. As noted in detail above, chronic inactivity impairs and reduces maximal oxygen consumption ( $VO_{2max}$ ), cardiovascular reserve, and fitness (35). Individuals with an inactive lifestyle and low level of fitness are more prone to develop coronary artery disease (CAD) and have greater odds of suffering myocardial infarction and death. A number of epidemiologic studies have demonstrated an inverse dose-response relationship between physical activity and mortality from CAD (36). The mechanism of this interaction is not known, but the current belief is that regular physical activity prevents or suppresses the chronic inflammation associated with atherosclerosis, CAD, and the metabolic syndrome (37–39).

A daily regimen of 30 to 45 minutes of endurance or aerobic activity will reduce the risk of CAD, non-insulin-dependent diabetes, hypertension, and breast and colon cancers. Encouraging lifestyle changes and promoting fitness and leisure physical activity for such patients are important aspects of prevention and treatment of CAD (40).

It is well documented that chronic exercises have anti-oxidant effect on several levels. Exercise training prevents or reduces low-density lipoprotein oxidation (formation of a powerful free radical, oxLDL), which has been implicated as a cause of endothelial cell damage and subsequent inflammation and development of atherosclerosis. Furthermore, exercise training can promote and improve endothelial cell function and release of nitric acid (41). As noted, inflammation plays a key role in CAD. Inflammatory markers such as C-reactive protein are reduced with exercise training, which may explain the beneficial effects of exercise on reducing mortality and morbidity associated with CAD (41). A study by Ambramson and Caccarino revealed that physical activity is independently associated with lower levels of inflammatory markers even in healthy subjects with no signs of CAD or other inflammatory diseases (37).

When physical inactivity is associated with other conditions causing muscle atrophy and weakness, the catabolic changes in muscle can be aggravated. For example, the elderly with age-related decreases in  $VO_{2max}$  from baseline are particularly affected by prolonged bed rest. Similarly, trauma combined with strict bed rest can accelerate the loss of muscle strength and protein breakdown. This effect is maybe due to hypercortisolemia associated with acute trauma, resulting in muscle catabolism. In one study, intravenous hydrocortisone given to immobilized persons resulted in three times the rate of catabolism seen at baseline (42).

## Prevention and Treatment of Muscle Weakness

### Principles

- Identify clinical and subclinical changes in strength, endurance, and physical function.
- Determine whether additional conditions exist that may exacerbate atrophy and weakness caused by inactivity, such as acute trauma or chronic disease.
- Ascertain the necessity for continued bed rest or immobility.

### Strategies

- Prevent muscle weakness by prescribing progressive resistive exercise, stretching, and aerobic exercise.
- In most cases, use a combination of specific exercises to address all aspects of muscle weakness, including exercise for flexibility, strength, endurance, and fitness.
- Remobilize the patient as quickly as possible; provide progressive mobility training.
- Encourage 30 minutes of walking and leisure activities for at least 3 days a week for the general population.

### Flexibility Exercise

Stretching to maintain optimal muscle resting length as well as viscoelastic properties is important for maintaining normal muscle function. Several animal studies indicate that passive stretching of striated muscle is associated with muscle hypertrophy, increase in muscle fiber area, increase in number of sarcomeres, and muscle fiber proliferation. In doing so, undifferentiated, quiescent myoblasts residing on the sarcolemma of muscle fibers (satellite cells) are activated and believed to be responsible for this stretch-induced muscle hypertrophy. Passive stretch is also a potent mechanical stimulus to influence gene expression and muscle proliferation. For example, both myogenin mRNA per microgram RNA and muscle cross-sectional area were significantly increased after 3, 6, 14, and 21 days of stretch (overload) in avian latissimus dorsi (43).

Muscle stiffness due to lack of stretch occurs through the reduction of the elongation properties of elastic and collagen fibers and myofibrils. It is also a result of structural changes in the muscle, such as muscle fiber angulations, reduction of sarcomeres in 18 series, and rearrangement of collagen fibers and their cross-links. Even a relative increase in muscle connective tissue may lead to muscle stiffness and reduction of joint motion. Muscles that cross two joints such as the hamstrings, gastrocnemius, and long back extensors are particularly prone to stiffness, even in healthy subjects with limited physical activity. In immobilized and inactive persons, however, this process is accelerated in the absence of activity-induced stretch. Stiffness and subsequent muscle belly shortening of two-jointed muscles can interfere with functional walking. Hip-flexion contracture at 35 degrees as a result of iliopsoas muscle tightness causes a 60% increase in energy consumption per unit distance during ambulation (5). Thus, daily stretching of a muscle for a half hour can prevent the loss of sarcomeres in series of the immobilized muscle and maintain elongational properties of muscle fibers and surrounding connective tissue, maintaining full ROM of joints.

### Strengthening (Resistance) Exercises

To prevent disuse weakness and deconditioning, daily physical activity should be encouraged, and progressive resistance exercise (PRE) using isokinetic or isotonic exercises done on a regular basis. A minimum of once a day muscle contraction at 30% to 50% of maximal strength for 3 to 5 minutes, three times a week for a single muscle group, may suffice to prevent muscle loss and weakness in otherwise mobile, active individuals. Strengthening exercise prevents muscle atrophy and improves strength and endurance by mediating the activation of muscle genes, enhancing mitochondrial function, and improving protein synthesis, causing muscle fiber phenotypic changes and muscle angiogenesis (Table 48-2).

Muscle strength can be increased by concentric or eccentric contractions performed isokinetically or isototonically. To improve or maintain strength, there should be 8 to 15 repetitions for each muscle group done twice with brief pauses between sets. There are many studies that indicate that strenuous eccentric exercises may produce muscle damage since CK may increase 50-fold and cytokine and interleukin-6 (IL-6)

**TABLE 48.2** Resistance/Strengthening Exercises Guide

- Establish one repetition maximum for each muscle group.
- Select initial and subsequent intensity at 50%–80% of the maximum.
- Repetition is performed 8–15 times, twice per session for each muscle group, three times per week or more.
- Progressive increase in resistance (i.e., weights) and time until goal is achieved.
- Include sequentially all muscle groups of the lower and upper limbs, back and abdominal muscles.
- Focus on antigravity muscles, agonists, antagonists, and functional training.
- Exercise should become a habit and part of a person's wellness program.

fivefold. Furthermore, high-intensity eccentric exercises in untrained individuals frequently produce elevation of myofibrillar enzymes in plasma, ultrastructural damage of muscle fibers, infiltration of mononuclear blood cells, and acute inflammation (44). Therefore, it is important that eccentric exercises are started with lower intensity, fewer repetitions, and slower progression of applied resistance or loads.

Muscle weakness can also be prevented by the use of electrical stimulation. For example, applying local stimulation to the quadriceps while in a long leg cast may help preserve muscle bulk and strength and also may shorten rehabilitation time, a factor that may be particularly important in an athlete (45). For astronauts exposed to prolonged periods of microgravity with resulting muscle atrophy, functional electrical stimulation (FES) has prevented atrophy when applied 6 hours/day, with 1 second on and 2 seconds off stimulation at 20% to 30% of maximum tetanic force applied to the two pair of agonist-antagonist muscles in the legs (46).

For chronic disuse atrophy with weakness and stiffness, strengthening and stretching exercises may be required for several months, and, even then, return to normal strength and ROM may not be complete. For example, returning to normal functional capacity and fatigue resistance after 8 weeks of immobilization in persons with ankle fractures required 10 weeks of supervised physical therapy, demonstrating that more time is needed to restore muscle capacity than to develop muscle weakness (47).

### Exercises for Endurance and Fitness

Aerobic exercise should be prescribed for physically inactive individuals with history of prolonged bed rest, immobility, or limited physical activity regardless of age and sex and for those with high risk for CAD and metabolic syndrome. Covertino (48) and others have reported that decline in  $\text{VO}_{2\text{max}}$  is progressive and parallels the duration of bed rest and it occurs independently of age, sex, and the presence of any other disease and it is considered a major factor for the loss of cardiovascular fitness. Daily endurance exercises at 60% to 80% of  $\text{VO}_{2\text{max}}$  or at the target heart rate are required to maintain or improve aerobic capacity ( $\text{VO}_{2\text{max}}$ ) in persons with deconditioning

or for those who desire to improve their fitness. If resistance exercises are performed on a regular basis for 8 weeks or more, improvements in endurance,  $VO_{2max}$ , and cardiovascular fitness can also be expected (35). Daily or three to four times per week resistance or aerobic exercise to the muscles of the lower and upper limbs should be prescribed for 2 to 3 months to restore and increase endurance and fitness (49).

Short-time exercises can also prevent, attenuate, or reverse the process of deconditioning and functional decline during the period of bed rest. For example, high-intensity and short-duration isotonic ergometer exercises can maintain work capacity, plasma and red-cell volume, reverse negative water and electrolyte balance, and decrease the quality of sleep and concentration when compared with a no-exercise group during bed rest. However, isokinetic exercises, high-intensity short-duration, can only slightly attenuate the decrease in peak  $VO_{2max}$  and the loss of red-cell volume but not loss of plasma volume, cannot reverse negative water balance, and have no effect on quality of sleep and concentration (50). These studies have pointed out that different training protocols are required to reverse or prevent the adverse effects of inactivity.

Regular physical activity and exercises do provide anti-inflammatory effect in conditions with low-grade chronic inflammation such as CAD or type II diabetes resulting in the reduction of inflammatory cytokines and increased production of anti-inflammatory cytokines (51). Regular endurance exercise also activates a number of genes, enhancing their expression and leading to the production of oxidative muscle fibers (type I and type IIa) and phenotypic changes of muscle fibers.

Changes in motor unit recruitment and force of contraction further contribute to the loss of endurance and easy fatigability of immobilized subjects (52). Current international guidelines suggest that 30 minutes/day or 3 to 4 hours/week

of aerobic exercise should be enough to improve fitness and prevent cardiovascular deconditioning. One to two hours per week of this activity needs to be of higher intensity (40).

## JOINT CONTRACTURE

While joint contractures can be associated with a primary joint pathology, they more frequently result from a combination of contributory conditions coupled with a lack of joint motion. Changes resulting in limited joint motion may stem from joint pain, arthropathies, paralysis, capsular or periarticular tissue fibrosis, or muscle belly tendon changes. However, the single most common factor that contributes to the occurrence of fixed contractures is a lack of joint mobilization throughout the full allowable range. For instance, prolonged elbow immobilization in a flexed position will cause reduction of resting muscle length of flexors and capsular or soft-tissue tightness with resultant fixed joint contracture (53).

Many factors, such as limb position, duration of immobilization, and preexisting joint pathology, affect the rate of contracture development. Edema, ischemia, bleeding, and other alterations to the microenvironment of muscle and periarticular tissue can precipitate the development of fibrosis. Advanced age is also a factor since both muscle fiber loss and a relative increase in the proportion of connective tissue occur in the elderly (54). Microvascular changes and relative ischemia as found in diabetes mellitus can predispose to contractures, especially of the hand. Contractures that are precipitated by pathologic changes in the joints or muscles may be classified into three groups (Table 48-3): arthrogenic, myogenic, and soft tissue related. It is important to remember that all tissues surrounding a joint are likely to eventually become affected in joint contracture regardless of the initiating process.

**TABLE 48.3 Anatomical Classification of Contractures**

Type	Primary Cause	Secondary Cause
Arthrogenic	Cartilage damage, congenital deformities, infection, trauma, degenerative joint disease Synovial and fibrofatty tissue proliferation (e.g., inflammation, effusion) Capsular fibrosis (e.g., trauma, inflammation) Immobilization as primary cause	Immobility Immobility Lack of ROM Mechanical position
Soft and dense tissue	Periarticular soft tissue (e.g., trauma, inflammation) Skin, subcutaneous tissue (e.g., trauma, burns, infection, systemic sclerosis) Tendons and ligaments (e.g., tendinitis, bursitis, ligamentous tear, and fibrosis)	Immobility Immobility
Myogenic		
Intrinsic (structural)	Traumatic (e.g., bleeding, edema) Inflammatory (e.g., myositis, polymyositis) Degenerative (e.g., muscular dystrophy) Ischemic (e.g., diabetes, peripheral vascular disease, compartment syndrome)	Immobility Fibrosis
Extrinsic	Spasticity (e.g., strokes, multiple sclerosis, spinal cord injuries), hypertonicity Flaccid paralysis (e.g., muscle imbalance) Mechanical (e.g., faulty position in bed or chair) Immobilization as primary cause	Immobility Lack of stretch Faulty joint position Immobility Lack of stretch
Mixed	Combined arthrogenic, soft-tissue and muscle contractures noted in a single joint	

## Mechanical Properties of Connective Tissues

Connective tissue can be subdivided into five major groups: (a) loose connective tissue, (b) dense connective tissue (i.e., ligaments), (c) cartilage, (d) bone, and (e) blood vessels. Loose and dense connective tissues are complex, dynamic structures that are important for structural support, stabilization, and movement. It is not always well appreciated that these are living, changeable tissues that can adapt their structure and composition in response to a change in environment, particularly in response to mechanical stresses. An appreciation of the anatomic design is important to fully understand the mechanical properties of the loose and dense connective tissues and their relationship to passive stretch. Both types of connective tissues are composed of cells (fibroblasts) and intercellular macromolecules surrounded by polysaccharide gel, also called extracellular matrix. The intercellular substances, or collagen, impact the mechanical properties of the tissue, whereas the cells are important for homeostasis, adaptation, and repair functions (55).

### Collagen

There are two types of intercellular substances in connective tissues: collagen fibers and proteoglycans. Fibers in tendons, ligaments, joint capsules, and muscle endomysium and perimysium are predominantly of the collagen type, although there is a significant population of elastic fibers in tendons. This is consistent with function in that tendons have great tensile strength and some elasticity that allows a joint complex to move through all stages of muscle contraction and relaxation. Ligaments, on the other hand, are relatively inelastic and are composed primarily of collagen fibers. Collagen is the most abundant protein in the body and accounts for more than 20% of total body mass. At least 12 different collagen types have been well-characterized. More than 30 different genes produce different aggregations of specific polypeptides, resulting in the different collagen types.

The terminology used in describing the organization and aggregation of collagen molecules is inconsistent and confusing. All collagen molecules have a unique protein conformation known as the triple helix, a result of three constituent polypeptide chains of the collagen molecule coiled together. The synthesis of these chains from amino acids, known as pro-chains, occurs in the rough endoplasmic reticulum of the fibroblast. The precise amino acid sequence differs between the different types of collagens and accounts for the tissue-specific properties. When the collagen molecules (monomers) are subsequently secreted from the cell, enzymatic cleavage of the end-part of the molecule occurs, and the molecules aggregate in a systematic manner to form fibrils in the extracellular space (56). Collagen fibrils, visible with the electron microscope, are grouped into fibers that are visible with the light microscope. Cross-linking between collagen fibrils is another important structural feature that varies with location and function. The type and location of collagen cross-linking are the key to tensile strength and can be altered, depending on the direction and magnitude of applied mechanical loads. The

fibers aggregate into fiber bundles that are grouped together into fascicles. A large number of fascicles form the whole tendon or ligament (57). In striated muscle, collagen fibers form endomysium around the muscle bundles and perimysium around the muscle fascicles. These are covered with thin films of loose or dense connective tissues surrounding collagen fiber bundles of tendon or ligament (endotendon or endoligament), fascicles (peritendon or periligament), and the whole tendon or ligament (epitendon or epiligament). The epitendon and epiligament, as well as endomysium, are thought to be critically important in responding to mechanical loads and injury, and all play a part in the onset of myogenic, arthrogenic, or soft-tissue contractures (58).

In tendons and ligaments, type I collagen predominates, although types III, IV, and VI are also present. Important variations in collagen diameter have been found in association with site, age, activity level, and repair. Investigations in several animal and human models alike have demonstrated that changes in collagen diameter, density, and orientation follow Wolff's law; that is, connective tissues orient themselves in form and mass to best resist extrinsic forces. This has been established in response to physiologic conditions (e.g., immobilization or exercise) as well as in response to injury. Changes in collagen are mediated by fibroblasts that are sensitive to mechanical stimuli, enzymes (collagenase and tissue inhibitor of metalloproteinases), and growth factors. These factors shift the dynamic equilibrium toward synthesis or degradation, depending on environmental factors (59). If extrinsic factors, such as stretch or weight bearing, are limited, or if a joint is immobilized in a foreshortened position, then collagen fiber density and mass will be readjusted to the new positions or to new loads, reducing ROM of a joint and breaking point of ligaments and tendons (60).

### Proteoglycans

Although proteoglycans make up only about 1% of the dry weight of ligaments and tendons, their functions of lubrication, spacing, and gliding are essential (61). Proteoglycans also impact the viscoelastic properties of dense connective tissues. There are several different types of proteoglycans (e.g., hyaluronic acid, chondroitin sulfate, decorin, aggrecan, biglycan) that are specific to site and function. An examination of different regions of a tendon as it traverses around a bony pulley is an excellent example of adaptation of proteoglycans by dense connective tissues. The proximal region of the tendon (at a distance from the bony pulley) is only exposed to tensional forces and contains a scant amount of decorin providing some lubrication to the surrounding collagen fibers. By contrast, the region of tendon that is in contact with bone (and subjected to compression, gliding, and tension) contains approximately 10-fold more proteoglycans, most of which is chondroitin sulfate. In other words, the tissue is more like fibrocartilage in the area of compression to withstand the mechanical forces in that region. Work in animal models has demonstrated that these proteoglycan levels may adjust to environmental factors and be reduced by immobility (61).

### Disuse Changes in Connective Tissue

After trauma or inflammation of connective tissue, undifferentiated mesenchymal cells start to migrate to the site of injury and gradually change into mature fibroblasts. The fibroblasts travel along fibrin layers, multiply, and develop collagen-producing organelles (56). These new collagen fibers are either arranged randomly in the loose connective tissue or packed and oriented in the direction of force and stretch in dense connective tissue. Hence, the mechanical property of newly formed connective tissue is the result of the type and amount of collagen produced, as well as bonding and orientation of the collagen fibers and the intensity and duration of loading and stretching (53,57).

The balance between synthesis and degradation is disturbed by physical factors, such as the lack of static stretch that is seen in prolonged immobilization or immobility. Trauma with bleeding into the soft tissue and muscle, inflammation, degeneration, or ischemia could all trigger an increased synthesis of collagen. In these conditions, additional lack of stretch and mobility may cause the collagen fibers to become more tightly packed and randomly arranged (57).

The collagen in muscle connective tissue provides important functions, such as linking muscle cells and tendons, and is a supportive structure that holds muscle fibers and fascicles together. The synthesis of collagen tissue in the muscle is influenced by tension produced by muscular contraction, weight bearing, and stretching imposed by these activities. Hence, collagen synthesis in the muscle is greater during activity and reduced during immobility. Immobilization for 1 week causes 21% and 65% decreases in activity of the enzymes prolyl 4-hydroxylase and galactosylhydroxylase glucosyl transferase in nontrained and trained experimental animals, respectively (57,59). Collagen synthesis is reduced during immobility but proportionally less than muscle protein synthesis, and both can be reversed by resistance exercise and by stretching (19,21). Multiple factors play a role in development of joint contractures. The initial muscle stiffness and tightness in contracture formation is due to the myofibril protein titin, sarcolemma (containing collagen IV), and reduction of sarcomeres in series, as well as changes in the angulations of muscle fibers in respect to their origin and insertion. In the later stages of fixed contracture development, the connective tissues in the muscle, joints, and soft tissue become randomly oriented, tightly packed, and shortened in length, the processes mainly induced by the lack of physiological stretch and physical inactivity (33,62).

### Myogenic Contracture

Myogenic contracture is a shortening of resting muscle length that is due to intrinsic or extrinsic causes, limiting full ROM and causing abnormal positioning of the limbs or body. Intrinsic changes are structural and may be associated with inflammatory, degenerative, or traumatic processes. Extrinsic muscle contracture is secondary, resulting from neurologic conditions or mechanical factors. The diagnosis of muscle contracture should be made only after careful physical examination, which should include an evaluation of active and passive

ROM. Observing limitation of active ROM alone can lead to an erroneous conclusion since such limitation also could be due to muscle weakness.

Muscular dystrophy is an example of an intrinsic degenerative process in the muscle. The most significant histologic changes in this condition are muscle fiber loss, segmental necrosis, increased numbers of lipocytes, and fibrosis. The replacement of functional muscle fibers with collagen and fatty tissue in concert with chronically shortened resting muscle length results in contracture (63). Direct muscle trauma also can result in fibrosis. After hemorrhage into a muscle, fibrin deposition results initiating muscle fibrosis. After trauma, immobilization can independently increase serum CK activity, local vascular permeability, and swelling, all promoting development of myogenic or soft-tissue contracture (59).

Among the processes that may also cause intrinsic muscle shortening is heterotopic ossification. This is most commonly noted after trauma, joint surgery (especially of the hip), spinal cord injury (SCI), or other central nervous system injuries. The actual initiating factor is unknown. An alteration in local metabolism or blood flow, in connection with the systemic alteration in calcium metabolism that occurs with immobility, may be responsible for initiating this process. Although no truly effective treatment exists, ROM should be aggressively maintained. Surgical resection of the bone may be considered after the bone matures. Surgery for immature heterotopic ossification is often associated with a rebound phenomenon that worsens the extent of previous bone deposition. A single local radiation treatment may be used to limit recurrence. Prophylaxis can be accomplished through the use of disodium etidronate, a diphosphonate compound that prevents the calcification of ground substance, along with nonsteroidal anti-inflammatory drugs and with early mobilization (64).

Extrinsic myogenic contracture is the most common type occurring after multiple injuries and chronic illness, as well as in sedentary individuals. In planning a therapeutic approach, it is useful to identify the associated cause of an extrinsic contracture such as paralysis, spasticity, or biomechanics. If a paralyzed muscle cannot provide adequate resistance to its antagonists across a joint, then the stronger muscle will prevail and become shortened. A common example of this is the shortened triceps surae as seen in persons with chronic peroneal nerve palsy. Stretch applied to the muscle is essential to prevent contracture in these situations; however, strengthening of the weak muscle and proper positioning are also vital.

Similarly, in the presence of spasticity, a dynamic imbalance of muscle control exists across one or more joints. The resting length of spastic muscle is shortened because of increased muscle tone, which encourages faulty joint positioning and precipitating functional or fixed contracture development (see Fig. 48-2). In severe spasticity, it is often clinically difficult to identify the actual onset of structural changes in the spastic muscle. If full ROM is unobtainable even after prolonged stretch and tension, then fixed muscle shortening should be expected.

Mechanical factors can alone cause extrinsic myogenic contracture. Some degree of muscle shortening can be present even in healthy persons with reduced mobility and lack of exercise. In such situations, two joint muscles in the lower extremities are first to be involved since natural stretching during ambulation is reduced. The hamstring and back muscles are among the first to be involved; the iliopsoas, rectus femoris, tensor fascia lata, and gastrocnemius are next most likely to become shortened. In the upper limbs, the internal rotators of the shoulder and elbow flexors show most frequent contractures. The below-knee amputee with prolonged knee flexion while sitting will develop knee-flexion contracture as a result of tight hamstrings and soft tissue behind the knee. On the other hand, the below-knee amputee treated with a rigid postoperative dressing in full knee extension may develop quadriceps muscle tightness that prevents full knee flexion.

Patients with muscular dystrophy provide yet another example of contracture promoted by biomechanical factors. In muscular dystrophy, hip extensors often are very weak, forcing the patient into excessive lumbar lordosis to thrust the center of gravity behind the hip and in front of the knee joints; the patient tends to walk on his toes. Walking on the toes in full ankle plantar flexion prevents natural stretching of the triceps surae from occurring during the stance phase of gait, encouraging muscle shortening. If a clinician does not recognize this sequence of events, he or she might assume that weakness and fibrosis are the only reasons for a plantar-flexion contracture. A surgical lengthening of the Achilles tendon in such a case will not give the expected improvement. The lengthening of the tendon will actually shorten the muscle belly, decreasing plantar-flexor strength and diminishing the ability of these patients to walk on their toes. Because walking on the toes is the only feasible method of ambulation, the result of an ill-advised tendon lengthening may be a wheelchair-dependent patient (63).

### Arthrogenic Contracture

Pathologic processes involving joint components, such as degeneration of cartilage, congenital incongruity of joint surfaces, or synovial inflammation and effusion, are all accompanied by pain that fosters limited joint mobility, keeping the joint in less painful posture and fostering arthrogenic contracture development. In experimentally induced acute crystalline arthritis, exercise aggravates synovitis, whereas a short period of immobilization helps to reduce inflammation (65). In chronically induced experimental arthritis, however, joints immobilized for several weeks showed much greater destruction of joint cartilage than freely mobilized joints (66). Short-term immobilization is indicated in acute arthritis because of the presence of interleukin-1 in inflammatory synovial fluid. Studies indicate that passive ROM during acute arthritis may increase the release of interleukin-1, promoting interleukin-1 penetration into cartilage and binding to the receptors on the chondrocyte membranes and inhibiting the production of proteoglycans necessary for protection of cartilage (66). However, a study by van den Ende et al. clearly demonstrated that intensive dynamic exercise performed in addition to ordinary

physical activity in active rheumatoid arthritis patients did not induce worsening of the disease process, but rather, physical functioning of these patients was significantly improved. The authors concluded that an intensive exercise program is more effective than a conservative exercise program in improving the strength and functional capacity and does not worsen activity of the disease (67).

Cartilage loss and subsequent adhesions and pain cause muscle splinting, leading to loss in ROM and fixed contracture. The fact that pain and muscle splinting, not the loss of cartilage, are more responsible for the development of contracture is illustrated by patients with Charcot joint. These patients lack both pain sensation and proprioception but maintain relatively well-preserved ROM or even hypermobility of the involved joints in the presence of severe destruction of cartilage and joint surfaces.

The joint capsule also can lose its extensibility as a consequence of collagen fiber shortening, inadequate joint stretching, and faulty positioning (68). If the entire capsule is involved, ROM is compromised in all directions of movement. In the later stages of arthrogenic contracture, the periarticular tissue may also undergo histochemical changes (61). If repeated trauma with pain is combined with swelling and prolonged immobilization, periarticular tissue undergoes contracture development. In these situations, proteoglycan content is also decreased, contributing further to joint stiffness and contractures (61).

The shoulder and hip joint capsules often become symptomatic from contracture earlier than other joints. Initiating factors may include bicipital tendonitis, subdeltoid bursitis, rotator cuff damage, spasticity, or poor positioning coupled with immobility. However, posterior knee capsule shortening is a consequence of hamstring contracture or prolonged flexion positioning as seen in patients with wheelchair dependence for mobility (see Fig. 48-2) (68).

### Soft-Tissue Contracture

Cutaneous, subcutaneous, and loose connective tissue around the joint may also become contracted with immobility. Trauma to soft tissue with bleeding, for example, can initiate fibrosis, which may progress to contracture if joint movement is not allowed. In this situation, collagen fibers proliferate and are laid down in random fashion. In contrast to capsular tightness, soft-tissue shortening usually will limit movement in only one plane or axis. Burned skin is particularly susceptible to contracture. During recovery, burns that cross any joint must be ranged diligently and positioned to oppose the shortening forces of scarred tissue.

Vigorous active and passive ROM exercises, placement of the joint in a functional resting position, and use of compressive garments should be considered to prevent contractures in burn patients. Topical steroid and vitamin E applications have failed to reduce soft-tissue contracture or postoperative scar formation after reconstructive joint surgeries. Here again, adequate stretch and mobilization are important factors in the prevention of fixed contractures.

Ligaments also show biomechanical and biochemical changes during immobility. They become weaker and break easily. In experimental animals, the rate of growth, length of ligament, and elongational characteristics are influenced by tension applied to the ligament, growth hormones, size of underlying bones, and other unknown factors (68). A study in young, skeletally immature rabbits showed that the lateral collateral ligament of the knee could be elongated significantly (140%) when tension was applied for 6 weeks (69). A number of other studies indicate that physiologic stretch and tension are important factors in helping both growing and mature tendons and ligaments to maintain their mechanical properties, to withstand the stresses of weight bearing and mobility (7). Another cause for ligament weakness is decreased collagen synthesis. In addition, the ligament insertion sites on the bone show an increase in osteoclastic activity. During immobility, the fibroblasts of the cruciate ligament may assume a spindle shape with multiple cytoplasmic extensions and demonstrate reduced production of collagen fibrils, an important factor when considering ligament resistance to breakage (68). The disuse atrophy of collateral and cruciate ligaments can be prevented completely with resistive and ROM exercise in non-weight-bearing limbs. However, this exercise could not prevent significant bone loss in the femur and tibia in the same experimental animals (70,71). Another proof for deleterious effects of inactivity came from a study on middle-aged men who lived for 90 days in microgravity conditions. Half of them were placed on exercise regimens, performing fly wheel and isometric exercises every third day. Tensile deformation of Achilles tendon significantly decreased by 58% in nonexercising group. In the exercise group, this decline was 37% indicating that loading in this group was insufficient and did not prevent a decline in tensile property of tendon.

### Limitations of Physical Function due to Contracture

Contractures interfere with mobility, with the basic ADL, and with nursing care. Lower-extremity contractures alter the gait pattern and, in extreme cases, can prevent ambulation (see Fig. 48-2). A hip-flexion contracture, for example, reduces hip extension, shortens stride length, and requires the patient to walk on the ball of the foot with increased lumbar lordosis and increased energy consumption. For biomechanical reasons, hip-flexion contractures cause the hamstring muscles to shorten, which in turn flexes the knee. It is not uncommon to see a patient with hip contracture to develop progressive knee and ankle joint contractures, especially if the joints are not aggressively mobilized. Plantar-flexion contractures will cause an absence of heel strike and abnormal push-off, resulting in decreased momentum of forward progression. Hip extension contractures are not frequently encountered. Wheelchair ambulation is impaired by the advanced hip and knee extension contractures. Car transfers also may be difficult with the knee fixed in extension. Multiple joint contractures

can severely interfere with bed positioning and bed mobility, making perineal hygiene and skin care difficult. In addition, joint contractures tend to accentuate areas of increased pressure on skin, which may be impossible to prevent without first correcting the contracture. The mean oxygen consumption of walking with an immobilized knee in extension increases by 22.7%, and when knee and upper limb are immobilized, the consumption is increased to 24.7%. This suggests that arm immobilization (as occurs in stroke patients) minimally increases energy consumption, whereas a spastic leg with equinovarus positioning and knee extension will increase it significantly (72). Limitations in upper-extremity ROM may lead to impaired reaching, dressing, grooming, eating, and performance of fine motor tasks and skin care of arms and hands (5).

Prolonged bed rest may cause low back pain during bed mobility especially immediately after resumption of upright position and mobility. This pain is related to several factors, including tightness of the back and hamstring muscles as well as weakness of the back and abdominal muscles. Any shortening of these muscles will alter spinal alignment and posture, increasing spinal curvature and weight bearing on the small apophyseal joints. Abdominal muscle strengthening exercises as well as strengthening and sensible stretching of paraspinal and hamstring muscles, along with general conditioning, may prevent this common complication of immobility. Acute low back pain has been treated with bed rest; however, the therapeutic value of prolonged bed rest has been disproven. The study by Deyo et al. (73) and other investigators have reinforced the principle that prolonged bed rest should not be considered a therapeutic tool in the treatment of low back pain syndrome.

### Management of Contractures Analysis

A basic approach for initiating treatment for contractures is a careful determination of the predisposing factors, as well as knowledge of what joint components or tissues are actually involved. An observant neuromuscular examination emphasizing active and passive ROM and joint stability is essential. Particular attention should be directed to those muscles crossing two joints and to the application of special maneuvers to detect their shortening. In patients with severe uncontrolled spasticity, it may be necessary to obtain accurate ROM measurements with the use of regional or local nerve anesthesia; this is particularly helpful when surgery to repair a decubitus ulcer is contemplated. Of course, the best treatment is prevention, so a careful analysis of abnormal joint positioning and factors limiting ROM should be undertaken with any patient who is immobilized by disease or by the treatment of disease.

### Indication for Stretching and ROM Exercises

Once a contracture has developed, the *sine qua non* for treatment is active and passive ROM exercises combined with a sustained terminal stretch on a daily basis (Table 48-4). For

**TABLE 48.4 Basic Principles in the Prevention and Treatment of Contractures****Prevention***In healthy individuals with sedentary lifestyle, elderly.*

Flexibility exercises, stretch of two-jointed muscles, yoga, pilates

*In individual with preexisting condition or predisposition:*

Range-of-motion exercises (active or passive) with terminal stretch

Proper positioning in bed, wheelchair, splinting, casting

Early mobilization and ambulation (weight bearing)

CPM (continuous passive motion)

Resistance exercise to opposing muscles

**Treatment**

Passive range-of-motion exercises with terminal stretch

Prolonged stretch using low passive tension and heat (e.g., ultrasound)

Progressive (e.g., dynamic) splinting, casting

Treatment of spasticity; pharmacologic, motor point or nerve blocks using phenol, muscle injection of botulinum toxin A or B

Pain management

Surgical interventions (e.g., tendon lengthening, osteotomies, joint replacement)

mild contracture, sustained or intermittent stretching for 5 to 10 minutes daily may be effective. Prolonged stretches of 20 to 30 minutes or more combined with subsequent appropriate joint positioning and splinting are necessary for more severe contractures. This generally is more successful when used in combination with the application of deep heat at the musculotendinous junction or joint capsule. Ultrasound is the most popular heat source for large joints; its properties allow local heating in the presence of metallic implants and rapid increase of tissue temperature to the therapeutic level. Heating of the tissue to 40°C to 43°C will increase the viscous properties of connective tissue and maximize the effect of stretching (see Chapter 63, Therapeutic Physical Agents).

When applying terminal stretch to a joint, the proximal body part should be well stabilized. In many cases, slight distraction of the joint during stretch will prevent joint compression and possible soft-tissue impingement, particularly in the small joints of the hand. The shoulder is a common site of contracture, particularly in adducted and internally rotated positions. In this contracture, the normal downward sliding and rotation of the humeral head on the glenoid fossa do not occur, and forced abduction will, therefore, simply cause painful impingement of the rotator cuff tendon against the acromion. Stretch applied in forward flexion and external rotation will restore some of this motion and should be attempted before abduction.

Sustained stretch lasting 2 hours or more can be obtained by the use of splinting. Serial casting is the application of plaster or polymer bandages with careful padding over bony prominences. The cast is applied immediately after the use of heat and manual stretch to obtain maximal ROM. The cast

can be reapplied weekly. In patients with spasticity, chemical denervation (botulinum toxin injection) or local anesthetic injection before casting may improve positioning inside the cast and tolerance for wearing.

Dynamic splinting provides tension in the desired direction with the use of springs or elastic bands. This type of splinting is often used in the hand and arm because it allows a measure of function while providing stretch. Another way to provide a form of sustained stretch is to use a continuous passive mobilization (CPM) device. The use of these devices has become relatively routine for providing postoperative ROM stretching of the knee, and they have been adopted for use on other joints. CPM is recommended for the early mobilization of infected joints, synovectomized knees and hips, knee fractures, ligamentous repairs, some total knee joint arthroplasties, or any incipient myogenic or arthrogenic contractures. Early passive mobilization with CPM has been shown to promote the exchange of joint fluid, reduce the need for pain medication after surgery, and prevent contractures in high-risk patients. During CPM therapy, muscles around the joint remain relaxed, and pain is usually minimal. CPM is typically prescribed for 8 to 12 hours a day for a total of 3 to 5 days after surgery. When used alone, CPM is not effective in the treatment of fixed contractures.

To achieve optimal joint position, it sometimes is necessary to lengthen tendons by surgical means. The benefits and risks of tendon lengthening should be considered carefully. It must be remembered that the muscle belly will remain shortened or become even shorter when the tendon is made operatively longer; therefore, full active ROM may not be restored. Tendon lengthening combined with muscle transfer procedures in spastic, paralytic, or other contractures may give better results because the process attempts to restore equilibrium of the forces around the joint; this method is particularly effective at the ankle, using the tibialis anterior and posterior muscles. Electromyographic analysis of muscle function before tendon transfer will optimize results by ensuring the transferred muscle is innervated. In other situations, such as hip adductor contractures secondary to spasticity, tenotomy may be combined with obturator nerve neurolysis to obtain optimal results. In a chronic, fixed joint contracture that interferes with the patient's basic physical functions, the selection of the appropriate surgical procedure is of great importance (74,75).

**Prevention of Contractures**

Prevention of contracture in a bed-bound patient starts with the selection of an adequate bed and mattress, proper bed positioning, and a bed-mobility training program. The patient should be moved out of bed as soon as the medical condition allows. If bed rest is unavoidable, then bed positioning and bed-mobility training are incorporated into the patient's nursing management program. To assist a patient in turning side to side or in sitting up, partial side rails for grasp should be a standard part of bed equipment. An overhead trapeze is sometimes useful for patients with impaired bed mobility, allowing them to use their upper extremities to roll from side to side,

scoot up and down, attain a sitting position, and transfer into and out of bed.

For the patient with immobility that is due to paralysis or with compromised extremity function, a variety of assistive devices are used to keep the joints in functional positions. In addition to that, active or passive ROM exercises should be provided on a daily basis. Provision of daily ROM and flexibility exercises is essential for prevention of contracture in high-risk patients as well as in subjects with sedentary lifestyles. Encouraging the use of early and progressive ambulation or ADL for patients in recovery will help in maintaining the function of involved joints. Ambulation and weight bearing provide a physiological stretch and are an important approach for prevention and treatment of contractures.

## DISUSE OSTEOPOROSIS

Maintenance of skeletal mass depends largely on mechanical loading applied to the bone by muscle pull and the force of gravity. Bone mass will increase with repeated loading and will decrease with the absence of muscle activity or with the elimination of gravity (76,77). Certain populations are more susceptible to the effects of muscle inactivity or reduced weight bearing, such as the aging adult or the person with an SCI (78). Even healthy adults on bed rest lose bone at a rate that exceeds the rate of new bone formation, leading to osteopenia (79). Accelerated bone loss of tibia has been found in subjects on prolonged bed rest. Their losses of peak bone mineral density are similar to those in persons treated with chronic corticosteroids or with estrogen deficiency. Non-weight bearing over several weeks can cause trabecular and endosteal (and later cortical) mineral bone loss in the tibia, which requires 1 to 1.5 years to return to baseline level with normal activities (80). The bone mass begins to decline in the fourth and fifth decades of life, occurring most rapidly in women in the first 5 to 7 years after menopause (81), and the physical inactivity and non-weight bearing are significant additional factors for further loss of bone density. This loss of bone density and frequency of subsequent fractures were reduced in laboratory animals that were exercising during their growing age, indicating that exercise and physical activity during growth provide lifelong benefits to bone structure and fewer fractures in old age (82). However, this early benefit is compromised if a person becomes chronically deconditioned.

After an SCI, a mismatch occurs between bone growth and bone loss. Soon after initial injury, osteoblastic activity diminishes due to paralysis and non-weight bearing, and a rapid loss of bone occurs, resulting in severe osteopenia in the paralyzed region of the body (83). Furthermore, even relatively minor muscle dysfunction can result in bone loss regionally. Persons with rotator cuff ruptures have been shown to have significantly decreased bone mineral density as compared with controls, which is proportional to remaining shoulder function (84). Immobilization of forearms and wrists for a period of 5 weeks also resulted in loss of bone density in both men and

women, which was not ameliorated after 5 weeks of remobilization and hand therapy (85).

Immobilization or immobility primarily decreases bone formation, specifically in the zones of high turnover rate (primary spongiosa). When coupled with other risk factors, bone mineral loss could be significantly worsened. Animal studies showed that immobilization, estrogen deficiency, and calcium deficiency each can alone reduce cancellous bone density, but when combined, greater losses in bone volume and density are found. Estrogen and calcium deficiencies result in higher rates of bone resorption in contrast to the decrease in bone formation caused by immobility and non-weight bearing (86).

How much physical inactivity contributes to reduction of bone mass in paralyzed extremities is not entirely known. In patients with hemiplegia and lost mobility, the serum and urine indices of bone resorption did not decline with time from the onset of stroke but rather correlated to the duration and level of immobility. This suggests that disuse osteopenia resulting from combined immobility and paralysis is not self-limiting and that immobility is an important factor (87). A study of identical twins in which one of each pair had SCI demonstrated that the bone mass of the pelvis and legs continues to decline over time regardless of age and gender at onset (88).

Disuse osteopenia is characterized by a loss of calcium and hydroxyproline from the cancellous portion of long bone, epiphyses, metaphyses, and cortical bone near the bone marrow cavity. To what degree increasing bone resorption plays a part in the etiology of disuse osteoporosis needs further research. During 12 weeks of bed rest, bone resorption and osteoclastic activity occur relatively later as compared to the course of reduced bone formation in the process of establishing a new bone equilibrium (89).

It has been documented that with longer duration of immobility, an increasingly long time is required to restore bone density to the preimmobility level. Full body recumbency for 3 weeks in animals resulted in a loss of both trabecular and compact bones, which remained below baseline level even 2 months after free activity was again allowed (76).

## Prevention and Treatment

The importance of exercise training in preventing inactivity-induced osteopenia should not be underestimated whether for otherwise healthy or disabled individuals. Disuse osteoporosis can be prevented by regular use of isotonic exercises, weight-bearing and functional training. In rats immobilized by tail suspension, there were significant decreases in bone density and bone formation. Abnormalities were especially seen in trabecular bone. Animals that received specific limb exercise in addition to normal remobilization not only recovered bone mass parameters but also had improvement in the trabecular patterns, while nonexercised animals had persisting trabecular bone losses (90).

There is a great deal of evidence that resistance exercise can increase bone mass in humans. Studies have demonstrated that there is a significant correlation between muscle

strength and bone mineral density. For example, the strength of paraspinal muscles correlates with the mineral density of lumbar spine (91). Reduced back extensor muscle strength is associated with a higher incidence of vertebral fractures, thus suggesting that inactivity plays an important role in development of osteoporosis in women. Low mineral density of the spine can be improved with back extensor strengthening exercises (92).

In groups of patients with high risk for significant osteopenia, those either with paralysis or with hormonally induced osteoporosis, exercise should be provided to prevent fracture. Despite possible risk of pathologic fracture, weight-bearing and resistance exercise are particularly important in preventing progression of bone loss. Ambulation, or at least standing on a tilt table or in a standing frame, may retard the loss of calcium in those with SCIs. Additionally, in the elderly, exercise targeted at strengthening limb-girdle muscles and balance will lessen progression of bone loss and the chances of falls and pathological fractures as well (93).

### Principles and Framework

- Recognize immobility and the lack of exercise or loading as a risk factor acting either alone or in combination with other factors.
- Understand the structural, content and strength, bone changes in response to non-weight bearing and lack of muscle contraction.
- Understand the value of remobilization, weight bearing, and physical activity, including resistance exercises, in prevention and treatment.
- Calcium, vitamin D, and physical activity are essential in maintaining the healthy bones (94).

### Typical Prescription

- Progressive strengthening resistance exercise training for back extensors, hip extensors and abductors, and shoulder girdle muscles
- Posture, balance training, and long walks
- Avoidance of flexion exercise of lumbar spine or high-impact exercises in flexion position for those with vertebral fractures or advanced osteoporosis
- Controlled axial loading (use of a weighted vest) for reversing vertebral osteopenia

Evidence-based practice for prevention or treatment of osteoporosis and its consequences places regular exercises and calcium and vitamin D intake at the forefront of any management plan (95). In persons with impaired mobility and paralysis, that is, spinal cord injuries, additional interventions need to be used to prevent or treat this secondary osteoporosis. The bisphosphonates inhibit bone resorption and in addition inhibit calcium phosphate crystal formation (96). One bisphosphonate compound, tiludronate, has been used in paraplegic patients with some efficacy in maintaining bone volume without impairing bone formation (97). Salmon calcitonin is another compound that has demonstrated some success in maintaining

bone density and may be particularly helpful in patients who cannot be adequately mobilized (98).

### Immobilization Hypercalcemia and Hypercalciuria

Despite a normal serum calcium level, immobilized patients are markedly hypercalciuric. However, adolescent boys after acute SCI may show a significant hypercalcemia as well. Symptoms of hypercalcemia include anorexia, abdominal pain, nausea, vomiting, constipation, confusion, and, ultimately, coma (99,100). Treatment of immobilization hypercalcemia relies on achieving adequate calcium excretion through hydration with normal or one half normal saline and diuresis with furosemide. Patients with the end-stage renal disease on maintenance hemodialysis can also develop an acute hypercalcemia when placed on bed rest even for 3 days, which is difficult to treat except with remobilization (101). For immobilized healthy persons, urinary calcium excretion (hypercalciuria without hypercalcemia) increases above normal levels on the second and third days of recumbency. Maximum loss occurs during the fourth or fifth week, when urinary calcium excretion is double the level of the first week; on average, calcium loss is 1.5 g/week (94). This decrease in total calcium continues even after resumption of physical activity, and negative calcium balance can last for months and even years (79).

## EFFECTS OF INACTIVITY ON CARDIOPULMONARY FUNCTIONS

### Hemodynamic Alterations

Cardiovascular hemodynamic responses to bed rest, upright position, and immobility are related to body fluid distribution, inappropriate vasoconstriction of blood vessels in supine and upon assuming an upright position, and the inadequate pumping effect of the triceps surae during ambulation.

During prolonged recumbency, the resting heart rate increases by 1 beat/minute every 2 days, leading to immobilization tachycardia at rest and abnormal increases in heart rate on submaximal exercise and workloads. After 3 days of strict bed rest, heart rate increases 32% above the pre-bed rest response when resuming submaximal activity, 62% after 7 days, and 89% after 21 days of recumbency (102).

Assuming an upright position also provokes a significant increase in pulse rate, also related to the duration of bed rest, too. A healthy, active person's heart rate increases 13% on getting up from a supine position (103). Saltin et al. (104) found a pulse rate response on submaximal exercise of 129 beats/minute for active healthy persons, compared with 165 beats/minute at the same level of exercise intensity in persons after bed rest of 3 weeks.

The vertical column of arterial blood exerts significant pressure on the lower part of the arterial tree, provoking norepinephrine release and vasoconstriction upon arising, thus preventing shifting of blood and hypoperfusion of the brain. This

vasoconstriction is delayed or absent in persons on prolonged bed rest. When standing up, there is a shift of venous blood from the thorax and upper limbs to the legs, causing an increase in venous pressure to 80 to 100 mm Hg (102). Even a short bout of leg exercise will reduce the pooling of venous blood, thus normalizing static venous pressure to 25 mm Hg.

Other cardiovascular functions also change with prolonged bed rest. Stroke volume may decrease 15% after 2 weeks of bed rest, a response that may be related in part to blood volume reduction. Although heart rate response to submaximal exercise increases progressively, cardiac output is reduced (103,104). Diminished cardiac output coupled with reduced peripheral oxygen utilization causes a significant decline in maximal oxygen consumption ( $\text{VO}_{2\text{max}}$ ). After 20 days of bed rest,  $\text{VO}_{2\text{max}}$  may decline by 27%. Inactivity also alters the erythrocyte and platelet enzymatic antioxidant defense mechanisms, increases serum triglycerides, and decreases high-density lipoproteins (HDL) and apolipoprotein A1, which may contribute to development of atherosclerosis and increased cardiovascular morbidity (105,106). The alteration of cardiovascular function induced by immobility is commonly referred to as cardiovascular adaptation syndrome (CAS). If a patient with CAD develops CAS, cardiac ischemia may be aggravated. For example, orthostatic hypotension may precipitate the onset of angina in patients with CAD. One way of preventing CAS is to encourage early ambulation and graded activity. In the 1950s, patients with myocardial infarction were kept in bed for 2 to 3 weeks; today, they are encouraged to start walking on the second day. For those patients who, for some reason, cannot be mobilized, electrical stimulation of muscles can partially prevent the negative side effects of prolonged immobility. Electrical stimulation of thigh muscles in patients with refractory congestive heart failure significantly improved muscle strength and cross-sectional area (107).

### Alteration of Body Fluids in Recumbency

Normally, 20% of total blood volume is contained within the arterial system, 5% in the capillaries, and 75% in the venous system. Immediately upon lying down, 500 mL of blood shifts to the thorax and cardiac output increases by 24%. Estimated myocardial work is increased by approximately 30%. During lengthy periods of bed rest, there is, however, a progressive decline in blood volume, with the maximum reduction on day 14. This reduction in blood volume is due to a reduced hydrostatic blood pressure and decreased secretion of antidiuretic hormone. Plasma volume decreases more than red-cell mass, leading to increased blood viscosity and, possibly, to thromboembolic phenomena. The loss of plasma volume after 24 hours is 5%, whereas after 6 and 14 days, the loss is 10% and 20%, respectively, of the pre-bed rest level (108). The reduction of plasma volume can be diminished by exercise. Therapeutic isotonic exercises are almost twice as effective as isometric exercises in preventing plasma volume reduction (109).

In addition to plasma volume change, a reduction of plasma proteins is noted after prolonged bed rest. A short period of intensive exercise produces smaller losses of plasma

proteins, whereas sustained submaximal exercise actually induces a net gain in plasma protein, which also contributes to the stabilization of the plasma volume depletion (109). Hypovolemia, along with circulatory stasis that is due to bed rest, is an important precipitating factor in thrombogenesis.

### Orthostatic Intolerance

One of the most dramatic effects of prolonged bed rest is the impaired ability of the cardiovascular system to adjust to the upright position. After several days of bed rest, if a healthy person stands up from a supine position, the shift of 500 mL of blood from the thorax and abdomen into the legs occurs causing blood pooling because of impaired venous compliance and response to increased intravenous pressure. Venous return to the heart is reduced due to diminished venous compliance, an increase in venous pooling and intravascular volume depletion with end result of decreased stroke volume and cardiac output, and a significant decrease in the systolic blood pressure response on rising. In normal situations, blood pressure drop is prevented by immediate activation of the adrenergic sympathetic system. Baroreceptors in the right atrium, carotid arteries, and aortic arch trigger adrenergic reflexes releasing norepinephrine. The increase in plasma norepinephrine levels influences the release of renin and angiotensin II, which in turn potentiate the sympathetic vasoconstriction resulting in an immediate increase in pulse rate and restoration of blood pressure (110,111).

Normal orthostatic response after prolonged recumbency is significantly compromised. The circulatory system is unable to maintain a stable blood pressure and, for unknown reasons, is unable to mount an adequate sympathetic vasopressor response. Although plasma renin and aldosterone levels remain normal, blood pressure may fall more than 20 mm Hg upon rising up from supine position. The decrease in venous return triggers a rapid heart rate, which prevents optimal filling of the right ventricular during end diastole. Stroke volume, which depends on diastolic filling, may be insufficient to maintain adequate cerebral perfusion (112). The clinical signs and symptoms of postural hypotension are tingling, burning in the lower extremities, dizziness, light-headedness, fainting, vertigo, increased pulse rate ( $>20$  beats/minute), decreased systolic pressure ( $>20$  mm Hg), and decreased pulse pressure.

In healthy people, adaptation to the upright position may be completely lost after 3 weeks of bed rest. A significant increase in heart rate and decrease in systolic pressure may occur after only several days of recumbency in those with sepsis, major trauma, major medical illness, or advanced age. The process of restoring the normal postural cardiovascular responses can take 20 to 72 days. Older people are slower to restore normal blood pressure and heart rate after remobilization.

As a group, patients with tetraplegia are quite susceptible to orthostatic hypotension. When tilted up, they show a significant decrease in mean arterial pressure and an increase in heart rate. Both sympathetic and plasma renin activities are normal or slightly increased. Two possible mechanisms may

account for orthostatic hypotension in patients with SCI. First, the normal increase in plasma norepinephrine that occurs on tilting is delayed in patients with tetraplegia. Second, the successful use of compressive antigravity suits in treating postural hypotension indicates that venous pooling may play an important role in the occurrence of orthostatic intolerance (113).

Early mobilization is the most effective way to counteract orthostatic intolerance and should include ROM exercises, strengthening exercises in supine and upright positions, and progressive ambulation. Abdominal strengthening and isotonic/isometric exercises involving the legs are optimal for reversing venous stasis and pooling. Elevating leg rests and reclining backs or tilt-in-space wheelchairs are used to assist patients during the reconditioning process. Occasionally, a tilt table may be necessary, with the goal of tolerating 20 minutes at 75 degrees of tilt for SCI patients. Supportive garments such as elastic bandage wraps, full-length elastic stockings, and a variety of abdominal binders are used regularly. Ephedrine, midodrine, and phenylephrine are sympathomimetic agents that help to maintain blood pressure; fludrocortisone (Florinef), a mineralocorticoid, is the next choice of drug to use. Maintaining an adequate salt and fluid intake will prevent any worsening of hypotension secondary to blood volume contraction (110,113). Infusion of saline solution is also indicated when fluid volume and dehydration cannot be corrected by ordinary means (114).

### Impaired Cardiovascular Performance and Fitness

The efficiency of the cardiopulmonary response to muscle work demand depends on the frequency with which maximal work level is attained and the degree of physical inactivity. Because of close interaction between these two systems, the maximal cardiovascular capacity gradually declines with reduced physical activity (115). This decline of cardiovascular function is accelerated in chronically ill and disabled. The clinical signs of reduced cardiovascular functional fitness are not easily recognized especially if associated with other chronic conditions.

In recumbency and deconditioning, there is a gradual elevation of the systolic blood pressure in response to increased peripheral vascular resistance and increased heart rate. In addition, the absolute systolic ejection time is shortened, and the diastolic filling time reduced, resulting in stroke volume reduction. Work capacity, which is derived from left ventricular pressure and force of ventricular contraction, is also reduced. Overall declines in cardiac output and left ventricular function with prolonged immobility and inactivity have been reported in several studies (102,104).

Furthermore, reduced cardiovascular function and fitness are associated with a twofold increase in the risk of cardiovascular mortality and morbidity (116,117). The cardiovascular risk of inactivity is similar to that of hypertension, diabetes, and high cholesterol, and it is dose related. Increase in physical activity and regular exercises, on the other hand, reduces cardiovascular morbidity and mortality (118). A number of studies have found a dose-response relationship between higher physical activity and lower cardiovascular mortality (117).

Physical activity and exercise (even of moderate intensity) have a beneficial effect on other cardiovascular risk factors such as hypertension, type 2 diabetes, and obesity (118,119). Regular physical activity and appropriate diet can reduce the risk of type 2 diabetes by 58%. This percentage is even higher in people older than 60, who have a nearly one-in-five chance of developing type 2 diabetes. It has also been documented that even low levels of physical activity like walking have a beneficial effect on cardiovascular fitness (120).

Inactivity is a widespread chronic health problem. At least 25% of the U.S. population is not physically active at all and at risk for development of cardiovascular and musculoskeletal complications (115). In addition to the negative effect on nonexercisers, people who are active can benefit even more by increasing the intensity and duration of their activities (115). Many benefits of exercise training, however, can be lost within 2 weeks if physical activity is substantially reduced. These benefits are completely lost within 4 to 8 weeks if physical activity is not resumed.

### Immobility and DVT

Immobility exposes the patient to two factors that are contained in Virchow's triad and contribute to clot formation: venous stasis and increased blood coagulability. The third factor, injury to the vessel wall, is all that is required to further increase the patient's risk for thromboembolism. Paralysis and trauma to the lower limbs or pelvis may add to the risk for development of DVT. A direct relationship between the frequency of DVT and the length of bed rest has been observed (121).

In stroke patients, DVT is ten times more common in the involved extremities than in the uninvolved extremities. In non-ambulatory stroke patients, DVT is five times more frequent than in patients who can walk more than 50 ft (122). Although the first week of bed rest is the most frequent time for development of DVT, it may occur later during remobilization. When stasis is present, thrombus formation usually starts in the valve cusp of the deep veins. Stasis may contribute to anoxia and damage of the endothelial cells in the valve pocket, thus adding the third factor for initiating the onset of DVT. Whether stasis alone can result in DVT is not fully confirmed. However, several studies suggest that stasis may lead to increased formation of thrombin, which then leads to platelet aggregation and thrombosis (123). DVT mostly commonly forms in the veins in the calf. Usually, such thrombi will attach to the wall of the vein within 1 week; however, 20% of calf thrombi extend to popliteal and thigh veins, and half of these will embolize to the lungs, posing a serious threat to the patient's life (124).

Venous stasis in the lower extremities is mainly due to decreased pumping activity of the calf muscles and increased orthostatic pressure. Other factors that can contribute to stasis are surgery, age, obesity, and congestive heart failure, all of which can lead to abnormal blood flow mechanics. Also, contributing to the likelihood of DVT occurrence in the patient confined to bed is a hypercoagulable state, produced by decreased blood volume and increased blood viscosity and

associated with many conditions, such as malignancy or blood factor deficiencies.

Clinical detection of DVT begins with the observation of signs and symptoms, including edema, tenderness, hyperemia, venous distention, and Homans' sign. When DVT is suspected on clinical grounds, one or more of these additional diagnostic studies should be considered:

- *Doppler ultrasound study* may be 95% accurate below the knee DVT.
- *Radionuclide venography* is both sensitive and specific for thrombi above the knee.
- *Contrast venography* remains the standard for DVT diagnosis. However, it is invasive, time-consuming and irritating to the venous lining.

Pulmonary emboli are manifested by a sudden onset of dyspnea, tachypnea, tachycardia, or chest pain and often are associated with a preexisting DVT. Diagnosis rests on arterial blood gases, ventilation/perfusion scanning, and computed tomographic pulmonary angiography (CTPA).

The most common means of preventing thromboembolic complications is to use low-dose subcutaneous injections of heparin 5,000 units twice a day (125). Low molecular weight heparins (LMWHs), however, are more effective in prevention of DVT than subcutaneous injection of heparin after hip and knee surgery. Enoxaparin is a commonly used LMWH in a prophylactic dose of 30 mg subcutaneously every 12 hours or 40 mg once a day starting 12 hours postoperatively. Prevention of DVT in stroke or SCI patients can effectively be accomplished by LMWHs. The treatment of DVT without or with pulmonary emboli is also effective with LMWHs. Enoxaparin in the dose of 1.0 mg/kg subcutaneously every 12 hours or 1.5 mg/kg every 24 hours is used for inpatient treatment of DVT and for outpatient treatment, 1.0 mg/kg every 12 hours, until anticoagulation with oral agents is achieved. However, intravenous heparin is the treatment of choice for femoral or pelvic thrombosis and pulmonary embolism. The usual intravenous dose is load of 5,000 units, mix 25,000 units in 250 mL D5W (100 units/mL) and then infuse it in the rate of 11 mL/hour. The dose is monitored by activated partial thromboplastin time. For chronic treatment of DVT, warfarin (Coumadin) is a standard approach. The dose is monitored by the prothrombin time and the standardized international ratio, which should be in 2.0 to 3.0 range (126).

After the diagnosis of DVT is made and treatment with heparin and warfarin is initiated, ambulation can be permitted on the second or third day if the partial thromboplastin time is within the therapeutic range. Recent literature supports the conclusion that 5 to 7 days of bed rest is not necessary for DVT if a therapeutic level of anticoagulation is achieved before that time (127,128). Other preventive measures include external intermittent leg compression, elastic leg wrappings, active exercise, and early mobilization. After anticoagulation is established, the patient is remobilized and allowed to participate in ADL and mobility functions. Early remobilization will reduce swelling and

pain in the calf muscle but will not completely eliminate danger of pulmonary emboli, especially in the patients with a thrombus whose proximal end is unattached to the wall of a vein (127).

### Pulmonary Alterations

The respiratory complications of immobility are known to be life threatening. Initial pulmonary alterations result from restricted movement of the chest in the supine position and gravity-induced changes in the perfusion of blood through different parts of the lung. When venous and hydrostatic pressures that are due to gravity are increased in different parts of the lung, then perfusion is also increased. The balance between perfusion and ventilation is altered during recumbency (129). A change of position from upright to supine results in a 2% reduction in vital capacity, a 7% reduction of total lung capacity, a 19% reduction in residual volume, and a 30% reduction in functional residual capacity (130). Vital capacity and functional reserve capacity may be reduced by 25% to 50% after prolonged bed rest. Mechanisms responsible for this may include diminished diaphragmatic movement in the supine position, decreased chest excursion, progressive decrease in ROM of costovertebral and costochondral joints, and shallower breathing with a subsequent increase in respiratory rate.

Clearance of secretions is more difficult in a recumbent position. The dependent (i.e., usually posterior) lobes accumulate more secretions, whereas the upper parts (i.e., anterior) become dry, rendering the ciliary lining ineffective for clearing secretions and allowing secretions to pool in the lower bronchial tree. The effectiveness of coughing is impaired because of ciliary malfunction and abdominal muscle weakness. Regional changes in the ventilation-perfusion ratio in dependent areas occur when ventilation is reduced and perfusion is increased. This may lead to significant arteriovenous shunting with lowered arterial oxygenation. Atelectasis and hypostatic pneumonia may be the ultimate result of these alterations.

The intercostal and axillary respiratory muscles for deep breathing gradually lose their strength and overall endurance. Treatment or prevention involves early mobilization, frequent respiratory toileting, and frequent position changes. A patient in a recumbent position should be persuaded to perform regular pulmonary toileting and deep breathing and coughing exercises and to maintain adequate hydration. An incentive spirometer, chest percussion, and postural drainage with oropharyngeal suctioning can prevent aspiration and atelectasis. The presence of preexisting pulmonary disease requires the use of bronchodilators.

## GENITOURINARY AND GASTROINTESTINAL SIDE EFFECTS

### Genitourinary Alteration

Many compromises occur in the physical and metabolic functions of the urinary tract system. Prolonged bed rest contributes to increased incidence of bladder or renal stones and

urinary tract infections. Hypercalciuria is a frequent finding in persons who are immobilized. Other important factors include an altered ratio of citric acid to calcium and an increased urinary excretion of phosphorus. In the supine position, urine must flow uphill from the renal collecting systems to be drained through the ureters. Patients often find it difficult to initiate voiding while supine, a situation that is not ameliorated by reduced intra-abdominal pressure and weak abdominal muscles. Studies have demonstrated less complete voiding occurs in immobilized animals, leading to urinary retention and infection (131).

Incomplete bladder emptying (e.g., in patients with SCI or diabetes mellitus) places the patient at greater risk for stone formation. The most common types of stones are struvite and carbonate apatite, found in 15% to 30% of immobilized patients. Bladder stones allow bacterial growth and decrease the efficacy of standard antimicrobial treatment. Irritation and trauma to the bladder mucosa by stones can encourage bacterial overgrowth and infection. Urea-splitting bacteria then increase the urine pH, leading to further precipitation of calcium and magnesium (131).

Treatment of these problems lies first in prevention, which includes adequate fluid intake to reduce bacterial colonization, use of the upright position for voiding, and scrupulous avoidance of bladder contamination during instrumentation. Other therapeutic approaches might include acidification of the urine through the use of vitamin C, urinary antiseptics, and, in those populations at highest risk for stone formation, a urease inhibitor. Treatment of stones after they have formed may require surgical removal or the use of ultrasonic lithotripsy. Appropriate antibiotic selection based on urine cultures and sensitivity trials is required to eliminate urinary tract infection. If retention is suspected, postvoiding residual volumes should be measured several times a day with ultrasound scanning devices. After stroke or SCI, removal of the Foley catheter and initiation of voiding trails should coincide with sitting and ambulation training. The adverse effects of immobility will aggravate the function of urinary bladder with poor contractility of the detrusor muscle and deficient sphincter opening and coordination.

### Gastrointestinal Alterations

Gastrointestinal alterations induced by immobility are easily overlooked. Loss of appetite, slower rate of absorption, and distaste for protein-rich foods all lead to nutritional hypoproteinemia. Passage of food through the esophagus, stomach, and small bowel is slowed in the supine position. An upright position increases the velocity of the esophageal waves and shortens the relaxation time of the lower esophagus (132). Thus, sleeping on two or three pillows with the upper trunk elevated in bed has therapeutic implications in preventing and treating reflux esophagitis. The transit of food through the stomach is 66% slower, and gastric acidity is higher in the supine position than when a person is upright and moving around (133). Peristalsis and passage of food through the small bowel are reduced with prolonged bed rest. Absorption of food is also reduced. For example, calcium absorption during normal activity is 31% of

intake and is decreased to 24% during bed rest, and calcium excretion through the bowels in immobility is increased from an average 797 to 911 mg/day (134). This is also one of the reasons why activity is recommended in management of osteoporosis along with calcium and vitamin D.

Constipation is a common complication that results from the interaction of multiple factors. Immobility causes increased adrenergic activity, which inhibits peristalsis and causes sphincter contraction (134). The loss of plasma volume and dehydration aggravate constipation. In addition, the use of a bedpan for fecal elimination places the patient in a nonphysiological position, and the desire to defecate is reduced by social embarrassment. The end result can be fecal impaction, which requires enemas, manual removal, or, in extreme cases, surgical intervention (135).

Prevention of constipation requires an adequate intake of an appealing, fiber-rich diet, including raw fruits and vegetables, and intake of liberal amounts of fluids and regular exercises. Stool softeners and bulk-forming agents are helpful in maintaining bowel function. The use of narcotic agents should be limited because they slow peristalsis. Limited use of glycerin or peristalsis-stimulating suppositories, in combination with a regularly timed bowel program, will further assist in regulating bowel movement (136).

## METABOLISM AND ENDOCRINE SYSTEM ALTERATIONS

Daily human energy needs include basal metabolic activity, thermogenesis of food, and the need for ADL and locomotion. It is unclear whether basal metabolism changes during bed rest; this uncertainty stems from inadequate scientific studies on control of factors that could influence the basal metabolic rate during prolonged bed rest. Lean body mass decreases during bed rest, and an equal gain in body fat maintains constant body weight (137). The reduced lean body mass is associated with decreased metabolic activity of muscle, diminished utilization of oxygen and glucose, increased insulin resistance, and deteriorated musculoskeletal function directly affecting overall metabolic, endocrine, and immune system functions (138).

### Electrolyte Balance

Prolonged immobility, especially if associated with post-traumatic electrolyte changes, will alter balance of sodium, sulfur, phosphorus, and potassium. A decrease in total body sodium occurs in tandem with the diuresis seen early during bed rest. However, serum sodium levels do not correlate well with the severity of orthostatic intolerance described earlier. Hyponatremia in the elderly is manifested by lethargy, confusion and disorientation, anorexia, and seizures. Potassium levels progressively decrease during the early weeks of bed rest (136). Immobility alone rarely causes serious electrolyte disturbances, aside from the high calcium levels seen in immobilization hypercalcemia (83). Nevertheless, patients with multiple medical illnesses may be seriously affected by even slight electrolyte abnormalities that are caused by immobility.

### Hormonal Disorders

A lack of physical activity can cause altered responsiveness of hormones and enzymes. Although they may be clinically undetected during early immobility, numerous changes have been demonstrated to occur in the endocrine system. Significant carbohydrate intolerance has been noted as early as the third day of immobility, and peripheral glucose uptake may decline 50% after 14 days (138). The duration of immobility correlates proportionally with the degree of carbohydrate intolerance. The glucose intolerance induced by bed rest can be improved by isotonic, but not isometric, exercises of the large muscle groups (139). The reason for this intolerance is not lack of insulin but rather increased resistance to the action of insulin, resulting in hyperglycemia and hyperinsulinemia. Possible explanations include a reduction in number or affinity of insulin receptors or postreceptor changes in the target cells. Inactivity appears to cause a reduction in insulin-binding sites, predominantly on the muscle membrane (140).

There are several other hormonal effects, including an increase in serum parathyroid hormone, which is related to hypercalcemia from immobility, although its precise mechanism is unknown (141). Triiodothyronine (T3) blood levels are also elevated during immobility (142). In addition, a variety of alterations have been reported in androgen levels and spermatogenesis, in growth hormone response to hypoglycemia, in levels of adrenocorticotrophic hormone, and in catecholamine secretion from the sympathomedullary system (143,144). Serum corticosteroid levels during bed rest are increased, accompanied with increased excretion of urinary cortisol. Studies on bed rest for periods of 1 month or more have found that adrenocorticotrophic hormone levels were three times higher than baseline and required about 20 days of physical activity of returning to normal (144). By contrast, prolonged exercise has been shown to increase plasma hydrocortisone levels and decrease plasma norepinephrine levels.

### Free Radicals and Oxidative Stresses

Free radicals are highly reactive compounds that cause oxidation of a number of molecules, inducing inflammation in a number of organs. Free radicals produced in muscles have been implicated as a cause of muscular fatigue as well for a decline in mobility in the elderly population. To counteract their negative effects, the body must produce or ingest antioxidants. Antioxidants are enzymes, vitamins, or other types of compounds that are capable of reducing or preventing the harmful effects of free radicals. Vitamins E, C, and A (i.e., retinol) and nonvitamin compounds like glutathione peroxidase and superoxide dismutase are important antioxidants that are reduced in older adults and, possibly, in chronic immobility.

Whether free radicals interfere with metabolic processes in muscle and its contractility, causing functional limitation in mobility and ADLs, is not entirely known. It has been theorized that increased free radicals in elderly subjects may indeed cause decline in mobility function (145). However, there are no studies to prove that free radicals contribute to disuse atrophy

and reduced endurance in subjects on bed rest. On the other hand, there is ample evidence that free radicals cause inflammatory conditions such as in atherosclerosis. For example, oxidized low-density lipoprotein (oxLDL) plays a major role in the development of atherosclerosis and subsequent blood vessel inflammation, which is a leading cause of endothelial dysfunction, thromboembolic events, and ultimately to physical limitations and disability (146).

Regular exercises reduce LDL levels, improve insulin sensitivity, and reduce body weight and subsequent risks for cardiovascular disease. Furthermore, moderate-intensity regular exercise can reduce free radicals and positively affect the balance between antioxidants and free radicals reducing oxidative stress and therefore producing beneficial effects on morbidity and mortality of CAD.

Very high intensity, long duration, or sudden onset of strenuous eccentric exercises can cause muscle damage and trigger release of inflammatory cytokines, that is IL-6, and precursors of C-reactive protein, which are associated with development of chronic low-grade inflammatory conditions. However, regular exercise of gradually progressive intensity does not produce elevation of inflammatory markers such as C-reactive protein and actually can reduce their levels (37,145). Study by Tanasescu et al. further elucidated the difference in types of exercises. They found that aerobic exercises, walking and running or aerobic dancing, were associated with a lower risk of fatal or nonfatal myocardial infarctions, while swimming and bicycling were not (146). The mechanism of how physical activity prevents cardiovascular disease is not fully understood although it has a beneficial effect on its risk factors, for example, on cholesterol, HDL, triglycerides, hypertension, and diabetes mellitus.

### IMMUNE SYSTEM ALTERATION

Chronic physical and psychological stresses may alter immune system functions such as a reduction of tumor rejection and increase in tumor growth factors and protection against upper respiratory infection or worsening of some autoimmune conditions. In animal studies, exposure to long periods of physical restraint resulted in a significant decrease in number of lymphocytes, T-lymphocytes response, and mononuclear splenic cells as well as increase in plasma corticosteroid levels (147). Initially, it was believed that these alterations are due to immunosuppressive effects of increased corticosterone levels; however, adrenalectomy did not prevent these changes. On the other hand, improvement in immune system function has been found in subjects after moderate types of exercises or physical activities. For example, randomized studies revealed that daily brisk walking of moderate intensity enhances the host protective immune system function and reduces days of illness in half when compared to nonexercising subjects (41). Long-term highly intensive exercises like marathons actually produce immunosuppression and increased susceptibility to upper respiratory infections in these athletes. These effects are not

ameliorated with vitamin C, glutamine, or zinc, although carbohydrates given before or after running a marathon have been partially successful in reducing this infection through unclear mechanisms. It is currently believed that very intensive long-duration exercise may cause striated muscle damage releasing a preponderance of proinflammatory cytokines and suppression of immune function as demonstrated in marathon runners and cyclists (148). In immunosuppressed patients with advanced age and HIV infection, moderate exercise has shown to provide an enhancement in amount of immune system function.

## THE NERVOUS SYSTEM AND IMMOBILITY

Sensory deprivation is a silent hazard of prolonged bed rest. Healthy subjects placed on strict bed confinement for 3 hours and required to wear gloves, goggles, and earplugs to reduce sensory input experience hallucinations and disorientation. During prolonged bed rest, exposure to social and chronological cues, such as time of day and movement through space, are reduced causing emotional, cognitive, and intellectual declines (149).

Social isolation alone with preserved mobility can cause emotional lability and anxiety but usually does not cause any intellectual alterations. However, prolonged bed rest and social isolation together produce much greater alterations in mental concentration, orientation to space and time, and other intellectual functions. Restlessness, anxiety, decreased pain tolerance, irritability, hostility, insomnia, and depression may occur during 2 weeks of recumbency and social isolation. Furthermore, judgment, problem-solving and learning ability, psychomotor skills, and memory all may be impaired. Perceptual impairment can be altered even after 7 days of immobility (150). Lack of concentration and motivation, depression, and reduced psychomotor skills may drastically affect the patient's ability to maintain optimal level of functioning and independence. These behavioral effects of immobility may result in a lack of motivation and diminish the patient's ability to attain optimal healing and restoration of function. Balance and coordination also are impaired after prolonged immobility, and this effect appears to be due to altered neural control rather than muscle weakness (151).

An important strategy in the prevention and treatment of these complications is to apply appropriate physical and psychosocial stimulation early in the course of illness. Options for the treatment of these effects include group therapy sessions, attention to socialization, encouragement of family interaction, and avocational pursuits during evenings and weekends, as well as participation in regular physical activity and exercise. In a multicenter prospective study of older, noninstitutionalized women tested over 6 to 8 years, greater intensity of physical activity was associated with smaller declines in cognitive function, even when controlling for age, estrogen use, and comorbidities. The authors concluded that physical activity prevents decline in cognitive function in older women (152).

## CONCLUSION

In 1862, the English surgeon John Hilton advocated bed rest as a basic physiologic approach in the treatment of human illness. Since that time, bed rest has often been used indiscriminately in the treatment of acute and chronic illnesses. The complications of prolonged bed rest have been increasingly recognized and reported since the mid-1940s. After World War II, clinical investigators, starting with Deitrick et al. (153) in 1948, have shown that prolonged bed rest may cause multiple adverse effects in a number of organs and systems. During the 1960s and 1970s, studies on astronauts greatly advanced our knowledge of the deleterious effects of bed rest and weightlessness, making clinicians more aware of a wide range of adverse effects associated with prolonged bed rest and immobility. As a result, a great number of new epidemiologic and randomized studies in the last three decades have been conducted, which in a great preponderance have demonstrated significant benefits of physical activity and exercises on cardiopulmonary, musculoskeletal, and total body functions.

A new era of advocating exercise and cardiovascular conditioning has begun. Studies have indicated that prolonged bed rest and sedentary lifestyles have negative effects on health and function. These effects are magnified in persons with neurologic disease or in the elderly. The principles long advocated by rehabilitation medicine have contributed significantly to the current philosophy on the use and misuse of immobility.

# Treatment of the Patient with Chronic Pain

*We are but dwarfs standing on the shoulders of Giants (1,2).*

Pain is purely subjective, difficult to define, and often hard to characterize or interpret. It is currently defined as an unpleasant sensory and emotional response to a stimulus associated with actual or potential tissue damage or described in terms of such damage (3–5). However, pain has never been shown to be a simple function of the amount of physical injury; it is extensively influenced by anxiety, depression, expectation, and other psychological and physiological variables. It is a multifaceted experience, an interweaving of the physical characteristics of the stimulus with the individual's motivational, affective, and cognitive functions. The pain experience is in part behavior based on an interpretation of the event, influenced by present and past experiences.

*Acute pain* is a biologic symptom of an apparent nociceptive stimulus, such as tissue damage that is due to disease or trauma that persists only as long as the tissue pathology itself persists. The pain may be highly localized or may radiate. Acute somatic pain may be well localized, aching, and sharp, whereas acute visceral pain may be burning, cramping, and radiating. It is usually associated with upregulated sympathetic activity, tachycardia, hypertension, tachypnea, increased metabolic rate, and hypercoagulability. Acute pain is generally self-limiting, and as the nociceptive stimulus lessens, the pain decreases. Acute pain usually lasts a few days to a few weeks (4). If it is not effectively treated, it may progress to a chronic form.

*Chronic pain* is a disease process in which the pain is a persistent symptom of an autonomous disorder with neurologic, psychological, and physiologic components. Differing significantly from acute pain, it is defined as pain lasting longer than anticipated (greater than 3 months) within the context of the usual course of an acute disease or injury. The pain may be associated with continued pathology or may persist after recovery from a disease or injury. Due to the complex nature of chronic pain, many other definitions have been proposed. Some include factors such as the persistence of pain despite extraordinary measures in a nonacute setting or pain that is without apparent biological value (6). Operational definitions include aspects such as pain sensation, pain behavior, functional status, emotion, and somatic preoccupation (6). As with acute pain,

treatable chronic pain that is due to organic disease is managed by effectively treating the underlying disorder; however, no such identifiable organic disease may be evident. Chronic pain can mimic the qualities of acute pain except that associated signs of autonomic nervous system response may be absent, and the patient may appear exhausted, listless, depressed, and withdrawn. Chronic pain can have exacerbations that are triggered by progression of organic pathology, physiologic stress, or worsening emotional, social, and psychiatric problems. As these problems subside, the pain may improve. Chronic pain may also be highly persistent and reported as severe for years without remission.

Proper management of pain requires an understanding of its complexity and knowledge of the nonneurologic factors that determine its individual expression. The treatment of pain with physical modalities is as ancient as the history of humanity, but the use of interdisciplinary rehabilitation techniques has gained acceptance only within the past few decades.

## EPIDEMIOLOGY

Nearly everyone experiences acute pain. Its incidence approximates the cumulative total of all acute diseases, trauma, and surgical procedures. In studies of the general population, patients have identified the head and lower limbs as the most common sites of acute pain and have identified the back as the most common site of chronic pain (7).

Chronic pain is less frequently experienced but is reaching epidemic proportions in the United States. There are more than 36 million individuals with arthritis, 70 million with episodic back pain, 20 million with migraine headaches, and additional millions with pain that is due to gout, myofascial pain syndromes, phantom limb pain, and complex regional pain syndromes (CRPS) (8–11). The pain resulting from cancer afflicts approximately 1 million Americans and 20 million individuals worldwide. Moderate to severe pain occurs in about 40% of patients with intermediate-stage cancer and in 60% to 80% of patients with advanced cancer (12–14). Back pain, as a general condition, episodically affects nearly 75% of the population in most industrialized nations. It is estimated that at least 10% to 15% of the working population of industrialized nations are affected by back pain each year (9,10).

## ETIOLOGY

Chronic pain is not merely a physical sensation. In the affective component of chronic pain, most patients show a degree of depression, and many show anger, jealousy, and anxiety. For many individuals, depression is the primary factor in the perception or experience of pain. Fifty to seventy percent of patients with chronic pain have either a primary depression or a depression secondary to their pain syndrome. Chronic pain, with accompanying depression, often leads to extensive periods of reduced productivity as well as inactivity. Prolonged inactivity alters cardiovascular function, impairs musculoskeletal flexibility, and causes abnormal joint function (15–18). Prevention involves the encouragement of patient activity as soon as it is reasonable.

The motivational component of chronic pain is concerned with the vocational, economic, and interpersonal reinforcement contingencies that contribute to the learning of pain behavior and the maintenance of chronic pain. More than 75% of patients with chronic pain display adverse behavioral characteristics, including problems with job or housework, leisure activities, sexual function, and vocational endeavors (19). Sleep disturbances and depression are highly associated with chronic pain. The patient also may have significant functional limitations as a result of multiple previous surgeries with little success and prolonged convalescence, disuse/physical deconditioning syndrome, or opioid medication (20).

Chronic pain's cognitive component involves how patients think and the part that pain plays in their belief system and view of self. The more the patient perceives pain as a signal, requiring a reduction of activity and protection of the affected part, the more difficult it is for the physician to achieve compliance with exercise, stretching, and other elements of the treatment program. The memories of pain from acute pain episodes may significantly hinder a patient's recovery and contribute to chronic pain syndrome (21–23). Pain is often the result of sensory input, affective state, cognition, motivational, and memory factors, which requires a multidimensional evaluation process, including treatment interventions directed at those components most responsible for the pain experience (24–26).

## Pain Pathways

Pain is a central perception of multiple primary sensory modalities. This interpretive function is complex, involving psychological, neuroanatomic, neurochemical, and neurophysiologic factors of both the pain stimulus and the memory of past pain experiences. The peripheral mechanisms for sensing and modulating pain have been extensively studied during the past 30 years. The pathways for pain sensation, from the initial stimulus of the nociceptors to the central nervous system, are summarized in Figure 49-1 (27–31). There appear to be several descending systems that play a role in control of the modification of the ascending pain pathways, which are summarized in Figure 49-2 (28,31–35).

**FIGURE 49-1.** Central nervous system structures that modify ascending pain pathways. H, hypothalamus; IL, intralaminar thalamic nuclei; L, limbic system.

Polymodal nociceptors respond to stimuli that damage tissue. This stimulation results in impulses ascending in the A-delta or C fibers to the marginal layers of the dorsal horn of the spinal cord. The A-delta fibers primarily synapse in laminae I and V, whereas C fibers synapse primarily in lamina II. Deeper regions of the dorsal horn may be polysynaptically involved in the processing of noxious stimuli.

The major ascending nociceptive pathways are the spinothalamic and spinoreticular tracts, which involve both oligosynaptic and polysynaptic neurons. These oligosynaptic pathways are fast conducting, with discrete somatotopic organization resulting in rapid transmission of nociceptive information regarding site, intensity, and duration of stimulus. Further, the oligosynaptic tracts provide somatic information by way of the posterior ventral nuclei of the thalamus to the postcentral cortex. The sensory discriminatory characteristics are delineated from the neospinothalamic portion of the lateral spinothalamic tract and the nonproprioceptive portion of the dorsal columns.

**FIGURE 49-2.** Ascending pathways for pain sensation from nociceptors to the central nervous system. H, hypothalamus; IL, intralaminar thalamic nuclei; L, limbic system; PT, posterior thalamic nuclei; VPL, ventral posterolateral thalamic nuclei.

Polysynaptic pathways are slow conducting, with a lack of somatotopic organization resulting in poor localization as well as dull aching and burning sensations. The nociceptive impulses transmitted through this system result in suprasegmental reflex responses related to ventilation, circulation, and endocrine function. Pathways contributing to this slow-conducting system are the paleospinothalamic tract, spinoreticular, spinocollicular, and the dorsal intercornual, as well as the spinomesencephalic tracts. The polysynaptic tracts form the brain stem reticular activating system with projections to the medial and interlaminar nuclei of the thalamus. From these nuclei, diffuse radiation occurs to the cerebral cortex, limbic system, and basal ganglia.

There are multiple levels of processing and convergence of nociceptive information in its ascending transmission to the cerebral cortex. In addition, there appear to be several descending pain control systems that play a role in the control and modification of the ascending pain pathways. The most complete studies have been of the periaqueductal gray (PAG) region of the midbrain. Stimulation of the PAG neurons and the subsequent descending impulses result in release of endogenous opioids at the nucleus raphe magnus (NRM) and nucleus locus

ceruleus (NLC). Endogenous opioids activate the serotonergic cells in the NRM and norepinegic neurons in the NLC. The axons of both of these monoaminergic neurons descend in the dorsolateral tract to interneurons, predominantly in laminae I, II, and V. These monoamines activate opioid-secreting interneurons. The morphine-like transmitter released may vary, depending on what type of receptor in the periphery has been activated. Both A-delta and C afferent fibers are inhibited by descending influences in the dorsal horn. The opioid inhibitory interneurons may be influenced by intersegmental and descending pathways, but the intersegmental and segmental mechanisms have not been established. These interneurons may function either by presynaptic inhibition on the terminals with the primary nociceptive afferents preventing the release of substance P or by postsynaptic inhibition on second-order neurons. Cells in the raphe magnus are activated by ascending sensory pathways transmitted to the reticular formation as well as by descending input from cells in the PAG region.

Other descending monoamine systems include locus ceruleus to the dorsal horn interneurons, nucleus reticularis, magnicellularis to the dorsal horn interneurons, and the mesencephalic lateral reticular formation to the dorsal horn interneurons. It has been suggested that monoamines are involved with supraspinal and spinal nociceptive mechanisms. Hormonally based descending pathways have been described but are poorly understood.

### Gate Control Pain Theory

The gate control theory of pain was developed by Melzack and Wall to account for mechanisms by which other cutaneous stimuli and emotional states alter the level of pain (36). They suggested that within the substantia gelatinosa of the dorsal horn, there are interneurons that presynaptically inhibit transmission of nociceptive information to the ascending tracts. These interneurons are activated by large-diameter afferents and inhibited by small-diameter afferents. In addition, they suggested that the brain exerts descending control on this system, relying on the fact that cognitive factors are known to influence pain behavior.

Several studies have failed to provide support for the gate control theory. It remains significant, although incorrect in detail, in hypothesizing that nociceptive pain undergoes dynamic integration and modulation. The gate control theory of pain has altered the concept of pain as solely an afferent sensory experience, broadening the concept to include the affective and motivational factors involved in the human pain experience (37). The gate control theory has been modified extensively during the past 40 years (38). It still represents the first attempt to describe a pain-modulating system that responds to input by noxious stimuli, innocuous afferent impulses, and descending control.

### Biochemical Pain Theory

In the peripheral nervous system, the extent and duration of the response to the stimulus may be modified at the biochemical level within the neurons in the pain-conducting pathway;

this neural plasticity is manifest by short-term modulation and long-term modification of the excitability of primary sensory and central neurons. Chronic pain can alter the nociceptive pathways by activation-dependent plasticity (resulting in auto-sensitization and windup), modulation-dependent plasticity (resulting in heterosensitization and central sensitization), or modification of primary sensory neurons, which results in pain hypersensitivity. NMDA receptors may be involved in synaptic plasticity and postsynaptic sensitization in the substantial gelatinosa and higher brain centers. This modulation of the neurotransmitters that affect the flow of information can induce the stimulation of polysynaptic neuron, or it can pathologically alter the anatomic features of these neurons and their interconnections such that the normal nociceptive stimulus response characteristics are amplified (39).

The biochemical theory of pain has evolved since the discovery of endorphins. The endogenous opioid system consists of three families of opioid peptides: beta-endorphin, enkephalin, and dynorphin/neoendorphin. The beta-endorphins are primarily concentrated in the pituitary and the basal hypothalamus. The other endogenous opioids are distributed extensively in the central nervous system. The dynorphins/neoendorphins and enkephalins are found in the caudate nucleus, amygdala, PAG matter, locus ceruleus, and dorsal horn of the spinal cord. In addition, the enkephalins are found in the NRM and the thalamic periventricular nuclei. The dynorphins/neoendorphins are found in the hypothalamus and substantial nigra (32).

Endogenous opioids are involved in analgesia, as well as multiple other clinical events. There are at least seven different opiate receptors, of which the  $\mu$ ,  $\delta$ , and  $\kappa$  appear to be involved in analgesia (40). The others are associated with such functions as respiration, appetite, hallucinations, dysphoria, immune function, temperature regulation, memory, and blood pressure control. Beta-endorphins may function in the modulation of local blood flow and immune function (41). The discovery of multiple opiate receptors and multiple endogenous opioid compounds provides an explanation for the multiple effects of the endogenous opioids. Within the peripheral and central nervous systems, the enkephalins act as neurotransmitters and the  $\beta$  endorphins act predominately as hormones. Endogenous opioids are only one part of a complex modulatory system involved in the collating, processing, and filtering of information concerning tissue damage (42).

Neural plasticity has been observed in patients with chronic pain. Persistent pain has been shown to increase the strength of the polysynaptic response as well as the anatomic configuration of the pain conduction pathway. This may result in long-term alteration in the connectivity and organization of pain pathways. The consequence of this alteration is a "pain memory" that is evoked with minimal stimulation and results in a maximal nociceptive response (39,43). Of note, neuroplasticity allows for secondary development of hyperalgesia with chronic opioid usage (44). The modulation of pain may occur via pronociceptive or antinociceptive neurotransmitters at multiple neurons along the pain conduction pathway. Pronociceptive

neurons include WW glutamate, aspartate, and substance P. Antinociceptive transmitters include gamma-aminobutyric acid (GABA), serotonin, and acetylcholine (45,46). Other possible neural peptides having analgesia or antinociceptive properties are calcitonin, cholecystokinin, somatostatin, and neurotensin (41).

### Chronic Pain Theory

The chronic pain theory encompasses many of the physical, motivational, cognitive, and affective components of pain. The anatomic pain pathways are relatively clear and represent a mechanism for nociceptive pain in the animal model. Multiple pain mechanisms exist in the human model because of the complex integration of nociceptive stimuli, conceptual and judgmental factors, sociocultural influences, and the motivational and emotional states of the individual. Pain mechanisms include nociceptive pain, neuropathic pain, central pain, psychogenic, and operant pain. The human perception and reaction to pain are a blending of these mechanisms. The nociceptive pain mechanism is detailed in the pain pathways, as previously described, and represents pain originating from tissue damage, such as pain from cancer, degenerative joint disease, myofascial pain, and trauma. Neuropathic pain can originate from peripheral neurologic disease or injury. Central pain originates from denervation occurring after a cerebrovascular accident, spinal cord injury, or amputation. This pain may be due to a loss of the peripheral modulating influences on the central nervous system resulting in an unmodulated activity of afferent A-delta and C fibers.

Psychogenic pain is the interpretation of emotional distress as aversive and unpleasant sensation and its description in terms of pain language and behavior. The psychological states that are interpreted in this manner include anxiety, neurosis, hysteria, and depression. This mechanism of pain is often overlooked in patients with chronic pain.

Operant or learned pain behavior is often a major factor in chronic pain. Although the initial precipitating event causing the pain may be quite minor, the pain behavior is often long-lasting, owing to reinforcement by environmental influences. Pain behavior may be directly reinforced by family and physician attention or the delivery of medication. Indirect reinforcement (physical or psychological demands) occurs with avoidance of aversive consequences, which would have to be met if there were no pain. Operant pain behavior is also reinforced through a punishment cycle, when an injured party is overprotected and "punished" by outside factors if he or she begins to function more independently.

### Genetics and Pain

The genetic determinants have been evaluated in humans with clinical pain (47). The variability in pain syndromes has been associated with inherited genetic factors in back pain (48), fibromyalgia (FM) (49), menstrual pain (50), and migraine (51). Family and twin heritability estimates indicate genetic as well as significant environmental factors modulating pain (52,53). Polymorphic pain genes have been associated with

congenital insensitivity to pain (54), drug metabolism due to cytochrome P450 (55), familial hemiplegic migraine (52,56), FM (57), and reflex sympathetic dystrophy (58).

Gene therapy and other advances in molecular medicine may offer a means of enhancing antinociceptive receptors (cannabinoid—1 and 2, acetylcholine—m and n, opioid— $\mu$  and  $\kappa$ , adrenergic— $\alpha_2$ ) or blocking pronociceptive receptors (neurokinin—1- $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazolepropionate [AMPA], n-methyl-d-aspartate [NMDA]); acting directly on the calcium channels of pain fibers; or acting directly on membrane receptors, protein C-GAMA, or other areas of the central nervous system involved in the transmission of pain (59,60). Definitive applications of gene intervention in pain control remain to be developed.

### Resolution of Pain

Acute pain is frequently the result of tissue damage in which the initial pain leads to an increase in anxiety, which magnifies the pain experience. The amount of anxiety generated and possibly the level of pain seem to be more influenced by the setting in which the pain develops rather than personality variables. With the healing process comes a reduction or termination of the anxiety and acute pain perception. When acute pain, which functions as a warning signal, fails to respond to treatment with conventional medical therapies, illness behavior and chronic pain develop. The anxiety characteristic of acute pain is replaced by depression with hopelessness, helplessness, and despair. When pain relief fails, physical activities decrease and suffering and depression increase.

Acute pain usually resolves when the source of nociception is removed or cured and resolves quickly with application of appropriate pharmacologic or regional analgesic therapy. The cause of acute pain can be documented by physical examination findings and diagnostic procedures. When indicated, appropriate operative intervention can be performed on the basis of these findings. A short course of analgesic medication usually controls postoperative pain, and a return to full, painless function can be anticipated in a matter of weeks. Acute pain control requires the administration of an efficacious analgesic dosage. Too little analgesia promotes suffering and anxiety, thus defeating the purpose of prescribing medications. Fear of drug addiction contributes to the underutilization of analgesic medications, and physicians tend to undermedicate in terms of frequency and dosage of pain medications (61,62). By prescribing low oral doses of opioids at infrequent intervals, physicians inadvertently force patients to adopt pain behavior in order to obtain adequate opioid analgesia. Pain behavior is characterized by high verbalization of pain, dependency, and the inability to work. Addiction in the acute pain situation is very rare, approximating less than 0.1% (63,64).

Unfortunately, a significant minority of acute pain patients continues to experience pain, which may progress into a more complex disease entity. Pain, a symptom of physiologic malfunction, now becomes the disease itself. Chronic pain represents a complex interaction of physical, psychological, and social factors in which the pain complaint is a socially

acceptable manifestation of the disease. The etiology of chronic pain may be persistent nociceptive input, such as arthritis or terminal cancer; psychological disorders, such as anxiety, depression, and learned behavior; or social factors, such as job loss, divorce, and secondary gain.

The optimal treatment for chronic pain is prevention. Once the disease state of chronic pain commences, reinforcers such as monetary compensation, presence of job-related problems, manipulation of the environment to satisfy unmet needs, and retirement from the competitive world obstruct complete disease resolution. Therapies designed for acute pain are often contraindicated for chronic pain.

Prevention of chronic pain requires identifying contributing factors and resolving them early in the acute stage. Aspects worthy of attention include psychological stress, drug or alcohol abuse, and poor posture or muscle tone, as well as significant psychological and operant pain mechanisms. Physicians should set a reasonable timeframe for the resolution of the acute pain process. Patients should be advised when the pain medication will no longer be needed and that those medications that are no longer effective will not be continued. The patient's attention should be directed to a gradual return of full activity on a prescribed schedule. Follow-up appointments should be planned at specified intervals so that the patient does not need to justify a visit. Work intolerance and job conflicts should be resolved.

### Pain-Reinforcing Factors

Chronic pain syndrome is a learned behavior pattern reinforced by multiple factors. These behaviors are frequently found in individuals who are depressed, are inactive, and lack the skills or opportunity to compete in the community. These environmental factors promote pain behavior, regardless of the etiology of the pain, thereby distinguishing the patient with chronic pain from the population at large. Patients often develop a new self-image and see themselves as disabled by their pain. This self-perceived disability justifies their inactivity and manipulation of others and attempts to collect compensation. The typical patient often has been unemployed, has low job satisfaction, or has been on sick leave for long periods of time (65–68). Our data indicate that individuals who have been removed from the labor market because of pain for less than 6 months have a 90% chance of returning to full employment; those removed from the labor force because of pain for more than 1 year have less than a 10% chance of return to full employment (66).

Individuals with chronic pain syndrome receive gains from their pain behavior; hence, they continue this behavior to maintain those positive reinforcers. Physicians reinforce the pain behaviors by lacking knowledge of this chronic disease process, failing to identify the chronic pain behavior and prolonging prescription of inappropriate medications, inactivity, and work limitations. The physician's failure to acknowledge and direct the patient toward recovery tends to validate the chronic pain syndrome by providing an undiagnosable and untreatable problem. Family members also frequently reinforce the chronic pain behavior. They allow the individual

to become inactive and cater to the patient's requests and needs over prolonged periods of time. In some instances, patients with chronic pain provide role models for pain or disability behavior for other family members (69,70).

## SOCIOECONOMIC FACTORS IN CHRONIC PAIN

Socioeconomic status likely plays an important role in the prevalence and risks of developing chronic pain. Persons with low socioeconomic status have an increased incidence of a variety of musculoskeletal pains including low back pain, as well as increased incidence of psychological problems. In a large cohort study of over 9,000 adults, lowest adult socioeconomic status (defined as having a "nonskilled" manual profession) was associated with a nearly threefold relative risk of chronic widespread pain, and at least a 1.5-fold relative risk for regional pain problems (71). Conversely, higher socioeconomic status (e.g., professional, managerial, and technical careers) was associated with a higher incidence of forearm pain (71).

### Worker's Compensation

In 1911, worker's compensation laws were enacted in the United States that required employers to assume the cost of occupational disability without regard to fault. These laws have dramatically influenced the recovery from injury. In many instances, they have become counterproductive; financial compensation may discourage return to work, the appeal process may increase disability, an open claim may inhibit return to work, and recovering patients may be unable to return to work. Often, the accident and resulting symptoms represent the patient's solution to life's problems (72). The pain literature suggests an enhanced pain experience and reduced treatment efficacy in patients with chronic pain who are receiving financial compensation (73).

### Litigation

Disability, along with pain and suffering, greatly determines the amount of compensation awarded in worker's compensation cases. The patient/client's pain behavior may be reinforced, maximized, and groomed with the hope of a large cash settlement. As a result of this reinforcement, the pain behavior develops into a learned response. The pain also becomes the disability for which the patient/client is seeking compensation. Therefore, a learned behavior becomes a determining factor in the amount of compensation awarded (74,75).

Alteration of the disability laws could decrease the number of acute pain patients who develop the behavioral disease of chronic pain syndrome. Changes that might discourage the development of chronic pain include allowing an injured worker to continue working at a job he or she is physically able to accomplish during the recuperation period, rapid adjudication of disability and compensation claims, and physicians restricting the patient's use of addicting and depressant medication to less than 1 month. The extensive use of

conservative intervention to include physical therapy and stress management early in treatment also could prevent the emergence of a chronic pain syndrome (76,77). For additional information on disability determination and medical-legal aspects, the reader is referred to Chapters 10 and 21.

## COMPLICATIONS OF CHRONIC PAIN

Chronic pain is an elusive disease complicated by iatrogenic, idiopathic, and psychosocial factors. These complications encompass physical, psychological, and environmental issues.

### Physical

The patient with chronic pain often develops secondary pain loci as a result of inactivity. Decreased range of motion, myofascial pain, and weakness because of disuse also may develop (78).

Medically induced drug addiction and dependence are particularly serious problems for both patients with chronic pain and their physicians (79,80). It has been estimated that 30% to 50% of patients with chronic nonmalignant pain have a significant drug dependency problem (81–85). Substance abuse, dependence, and addiction are negative prognostic factors in outcome studies (86). Treatment of the drug impairment is essential and results in a greater overall improvement in functioning (87).

### Psychological

Depression is a common complication noted with chronic pain (88). These patients often manipulate family, friends, and coworkers to achieve secondary gain. Chronic pain causes considerable distress to spouses and family members (89), and sexual dysfunctions (90) are common. Twenty-five percent of spouses report clinical depression and more than 35% rate their marriage as maladjusted (91). Insomnia is common and difficult to treat, but appropriate attention to sleep disturbances may help with other symptomatology (92).

### Environmental

Nearly one-third of the American population has persistent or recurrent chronic pain. One-half to two-thirds of these individuals are partially or totally disabled for varying lengths of time. It is estimated that 80 billion dollars a year (adjusted for the year 2000) are spent on medical needs, lost working days, and compensation (11,93). Data compiled in 1982 suggest that lost wages and social support systems cost the taxpayer \$15,000 to \$24,000 per chronic pain patient per year (94).

## ANATOMY OF PAIN

Knowledge of the peripheral anatomy of the human body is essential in evaluating the complex problems found in a patient with pain. The clinical problem is often reduced to

**FIGURE 49-3.** The connections and interchanges of the funiculi in the brachial plexus.

the simple question, “Is the pain in an area supplied by a single nerve root, a single peripheral nerve, or a branch of a peripheral nerve?” A physical examination to evaluate pain, weakness, and their distribution often leads the clinician to better localize the nerves involved in the patient’s report of pain.

### Somatic Innervation

A difficulty encountered in the diagnosis of pain is secondary to the overlap of cutaneous fields of segmental and peripheral nerves, as well as the overlapping innervation of muscle and bone. Single cutaneous nerves innervate sharply defined regions with little overlap, but these fibers regroup in the peripheral nerve and are again redistributed in the brachial or lumbosacral plexus. This makes it impossible to follow individual fibers from the dorsal roots to the areas innervated by the individual cutaneous nerve. Adjacent cutaneous nerves may be supplied by fibers from more than one spinal nerve (Fig. 49-3) (95). Anatomists and physicians have attempted to define areas of the skin, muscle, and bone that are of the exclusive domain of a single spinal cord root, as well as the areas of overlap. The size of these areas varies from nerve to nerve and from individual to individual. As with all knowledge of the human body, anatomy of sensation and pain rests on a foundation of original work performed by investigators too numerous to list. The figures in this chapter have taken some of the best work in the field and compiled it into a comprehensive review (Figs. 49-4 through 49-17). In delving into the literature in this area of anatomy, one cannot help but feel that he or she is standing on the shoulders of giants without whose work the figures in this chapter would be impossible.

### Dermatomes

Different techniques were used in determining the site and extent of innervation. Foerster’s (96) data were based on remaining sensibility of the skin innervated by an intact posterior root isolated by severing several nerve roots above and below. In determining the field of unaltered sensation, Foerster demonstrated considerable overlap of contiguous nerve roots. Similar techniques were used by Bing (97), the Armed Forces Institute of Pathology, and Haymaker and Woodhall (98). Keagan and Garrett (99) used hyposensitivity to pin scratch in cases of herniated intervertebral discs, which resulted in the most extensive dermatome map. Keagan and Garrett contended that no sensory overlap exists between dermatomes, which is contrary to most investigators’ experiences. Richter and Woodruff used the electrical skin resistance method (100,101) over sympathectomized areas of the skin. It is noted that dermatomes of almost all cutaneous nerves are beyond the anatomic boundaries noted on gross dissection. Clinical data suggest that areas of sensory deficit extend further proximally than mapped by Foerster, but not as far proximally as suggested by Keagan and Garrett. For this reason, the dermatomes used in the figures are derived from an interpolation of areas determined by personal experience and multiple other authors (96–104).

### Myotomes

The determination of muscular innervation is the result of the analysis by many observers of traumatic and surgical outcomes evaluated during the postoperative and recovery periods (98,104,105). The results of these analyses are provided in detail in Tables 49-1 and 49-2. The myotomes used in these drawings are derived from the experience of multiple clinicians.

Spinal segments in parentheses signify those that are occasionally present; those in boldface are the major segments supplying the muscle designated. Segments not in boldface are usually present but to a minor degree.

<sup>a</sup>The small branch from the radial nerve also innervates the brachialis muscle.

## Sclerotomes

Areas of segmental innervation of bone (sclerotomes) are closely linked with muscle innervation. Injury to bone, ligament, tendon, fascia, and other mesodermal structures of the body may result in pain referred in a sclerotomal distribution

(98,106). Notable references for peripheral nerve innervation of the skeleton include Haymaker and Woodhall (98), Dejerine (107), Foerster (108), and Brash (109). The peripheral nervous system of the skeleton is closely linked to muscle innervation. Most of the bones of the skeleton receive their innervation

**TABLE 49.2 Lower Extremity Muscle Innervation**

Spinal segments in parentheses signify those that are occasionally present; those in boldface are the major segments supplying the muscle designated. Segments not in boldface are usually present but to a minor degree.

from nerve twigs of the attached muscles. Some parts of the skeleton, especially the joints, receive branches directly from nerve trunks (99).

### Autonomic Innervation

The peripheral component of the autonomic nervous system is concerned with innervation of visceral glands, blood vessels, and nonstriated muscle. The relationship to pain has been confined to the visceral components in this section (104,105,110–112).

## DIAGNOSTIC AND CLINICAL EVALUATION

In establishing the etiology of pain, it is essential to consider its location, characteristics, its chronology, the limitations it imposes on the patient, and the results of previous therapy. This is accomplished by a thorough pain evaluation, including

a detailed history, comprehensive physical examination, and review of appropriate diagnostic tests. When making the treatment plan, practitioners should keep in mind that many radiographic findings do not correlate with the patient's clinical presentation, and that most physical exam findings can be nonspecific. Most pain patients present a complex array of physical, motivational, cognitive, and affective manifestations and therefore require detailed psychological and social evaluations. In the intensive effort to integrate these evaluations, it should be remembered that acute and ominous processes such as fractures, infections, and tumors must be ruled out, even if the patient has previously seen other providers.

### History

A detailed history of the pain report identifies the pain in terms of its origin, radiation, quality, severity, and time intensity attributes, as well as mode of onset, duration, time of occurrence,

and factors that aggravate and relieve it. Previous treatments for pain should be noted, including comments regarding usefulness in the reduction of pain. Medications currently being taken, as well as those used in the past, should be recorded, along with the patient's perceptions as to the results achieved by each. The details of physical therapy, including types of modalities, exercise, and effectiveness of regimes, should be recorded. An inquiry as to the patient's attempts at biofeedback, relaxation, and hypnosis is also helpful. Information regarding associated findings including sensory deficits, muscle weakness, and altered body function should be obtained. It should be determined whether compensation is involved and if the patient is working; if not, the employment history should be obtained. The physical examination and related diagnostic studies should be directed toward evaluating the painful site and related regions. This process is useful in acquiring objective data to substantiate the clinical history.

### Physical Examination

Physical examination begins when the patient is first seen and continues through every contact made with the patient. This provides the opportunity for the physician to evaluate how the pain affects motion and activities. Physical examination always includes examination of related spine and musculoskeletal components, as well as a neurologic evaluation. Painful regions need to be compared with normal areas on the contralateral side of the patient for sensation, temperature, and sensitivity to palpation.

Functional evaluation measures the appropriateness of the patient's functional capabilities for the level of impairment. Objective, quantitative measurements give a baseline with which to evaluate progress and long-term outcome. Specific tools are available to describe and classify functioning, such as the International Classification of Functioning, Disability, and Health (ICF) (113). The ICF characterizes the interaction between a health condition, personal attributes, and environmental influences. In this model, hierarchical levels categorize health-related states in increasing levels of detail to form a standardized description of the condition. Lists of categories relevant to specific diseases, known as ICF Core Sets, exist for different pain conditions including chronic widespread pain and low back pain (114–118).

## DIAGNOSTIC PROCEDURES

### Laboratory Testing

Laboratory findings in acute and chronic pain usually have no features distinct from those found with a primary disease. Drug screening tests of the blood and urine may provide valuable information as to the variety and type of pain medications being ingested. Serum drug level testing provides data to determine the bioavailability of medications being taken by the patient.

### Imaging

Radiographic procedures are extensively used in the evaluation of pain. Spinal radiography has minimal value in the

**TABLE 49.3** Indicators for Potentially Serious Conditions

Major trauma
• Vehicle accident
• Fall from height
Minor trauma or strenuous lifting
• Older patients
• Potentially osteoporotic patient
Age older than 50 or younger than 20
History of cancer
Constitutional symptoms
• Recent fever
• Chills
• Unexplained weight loss
Risk factors for spinal infection
• Recent bacterial infection
• Intravenous drug abuse
• Immune suppression
Pain that is worse when supine
• Severe nighttime pain
Severe or progressive neurologic deficit
Major motor weakness

evaluation of most low back pain conditions because of the equal prevalence of abnormalities in symptomatic and asymptomatic populations, that is, low specificity and poor predictive value (119,120). Specific indications for routine radiological evaluation for patients with back pain have been developed (121) (Table 49-3). In the specific diagnosis of low back pain with sciatica due to herniated nucleus pulposus, plain radiography has been shown to have minimal value (122,123).

Radiography, computed tomography (CT), and magnetic resonance imaging (MRI) demonstrate anatomic or structural disorders, which account for a low percentage of functional abnormalities. However, CT, myelography, and MRI are well established in the diagnosis of disc herniation and provide significant false-positive results in subjects with no history of back pain. Asymptomatic individuals are diagnosed as having abnormalities (24% to 50%) on myelography (124), discography (125), CT (126), and MRI (127). The clinical usage of diagnostic tests requires a careful correlation between clinical signs, symptoms, and test results. For additional information on imaging studies, the reader is referred to Chapters 6, 7, and 8.

### Psychological Evaluation

The assessment of psychological issues in the overall evaluation and treatment of patients with chronic pain is an important component of any pain management program (128). Psychological evaluation often involves the use of questionnaires, inventories, and the clinical interview. Psychophysical methods of pain assessment (129) (tourniquet test, cold pressor

test, and visual analog scales) often augment the psychological evaluation.

The *McGill Pain Questionnaire* (130) is an often-used instrument designed to measure three dimensions of the pain experience: sensory, affective, and evaluative. The *Minnesota Multiphasic Personality Inventory* (MMPI or MMPI-2) has been used in the United States perhaps more than any other psychological instrument in the assessment of personality factors contributing to the experience of chronic pain (88). The typical MMPI profile for a patient with chronic pain denotes increased levels of hypochondriasis, depression, and hysteria. Numerous MMPI typologies based on clustering algorithms appear to have clinical and demographic correlates for the patient with chronic pain. However, these clustering algorithms have not been shown to be useful in determining successful outcomes of multidisciplinary pain management programs. Numerous MMPI typologies based on clustering algorithms have been proposed for the patient with chronic pain (131). The clinical interview helps to identify the affective, motivational, cognitive, and personality components of the patient with chronic pain. The emphasis of this evaluation is on the patient's behavioral response to pain, adjustments to impairment/disability, primary/secondary gain, and motivation. The psychological evaluation will help clarify affective, cognitive, and motivational components of the chronic pain. In conjunction with pentothal (132–134) and amytal challenges (134–136), the psychological evaluation is helpful in differentiating patients with significant somatic/peripheral pain from mood disorders, somatoform disorders, factitious disorders, and conscience exaggerators (137).

### Electrodiagnosis

Electrodiagnosis is an objective neurophysiologic extension of the physical examination. It typically includes the determination of nerve conduction velocities and needle electromyographic (EMG) studies of individual muscles. In addition, somatosensory evoked potentials have expanded the armamentarium of the electromyographer in evaluating the peripheral and central nervous system (138). For additional information on electrodiagnostic evaluation, the reader is referred to Chapters 4, 28, 29, and 30. EMG and evoked potential studies demonstrate the pathophysiologic changes that are associated with or due to structural abnormalities. The documentation of existing pathology is vitally important to the comprehensive management of complex painful conditions. Careful clinical correlation is essential when interpreting all tests related to chronic pain (139).

### Anesthetic Procedures

The response of the body and mind to pain results in sympathetic nervous system and psychogenic responses. Although clinical examination and appropriate investigations can help in delineating the contribution of the various mechanisms in an individual patient, many patients do not exhibit clear-cut mechanisms of pain. In these patients, differential diagnostic blocks may be valuable. Clinicians using differential blocks are frequently impressed by their usefulness in pointing to

mechanisms not suspected when considering the results of previous clinical examinations and laboratory work-up (140–142). For further information on anesthetic procedures, the reader is referred to Chapter 67.

## CLINICAL MANAGEMENT

The primary goals of treating a patient with pain are alleviating the pain and enhancing the patient's quality of life and functional capabilities. The management of acute pain is based on pharmacologic, psychological, medical, and surgical innovations or advancements within the past century. And yet, the management of chronic pain has been recognized as a major health care problem only in the past 25 years. It remains unclear why some people become patients with chronic pain and others resolve their acute pain without significant difficulty.

### Multidisciplinary Approach

The chronic pain problem is clearly multifaceted. No single physician has the resources to care comprehensively for the complex psychological, social, legal, medical, and physical problems involved in chronic pain. Therefore, the multidisciplinary team approach is necessary. Using a multidisciplinary approach does not mean the patient is referred from one specialist to another, because this tends to result in conflicting and overlapping treatment and a loss of hope of treatment in the patient. Ideally, the team should work together to provide a unified explanation of the illness and a comprehensive treatment program. The multidisciplinary pain service has the advantage of offering a variety of coherent treatment approaches to the patient. This type of program recognizes that a multifaceted problem requires a multifaceted approach, as well as continuity of care in which the patient is an active participant (143).

The core group for the multidisciplinary treatment service should include a physiatrist, a pain medicine physician, a neurologist, a physiotherapist or occupational therapist, and a psychiatrist or clinical psychologist. This group may vary considerably according to local needs, resources, and available expertise. However, the team must have the knowledge to manage the psychological and social problems with optimal medical and anesthetic treatments. They must also have a thorough understanding of physical treatments and the rehabilitation process.

The multidisciplinary pain approach begins with a complete clinical evaluation. Comprehensive medical and psychosocial evaluations with particular emphasis on functional capabilities and behavioral responses to pain are essential. The somatic, affective, cognitive, and emotional components of the chronic pain experience are explored. All previous medical records are needed to avoid repeating appropriately performed studies and unsuccessful treatment approaches. This comprehensive clinical evaluation also includes functional capabilities to determine impairment level. The psychosocial evaluation focuses on the behavioral response to pain, adjustments to the physical impairment, and degree of motivation (144). The MMPI-2 and other written tests are often used for generalized screening.

The multidisciplinary team functions at several levels within the treatment process. It attempts to identify and resolve documentable organic problems when present and to improve the patient's ability to cope with the pain through medication, psychological intervention, and patient education. In addition, considerable effort is devoted to improving the patient's functional outcome as measured by increased activity time, improved activities of daily living, increased distance walked, and increased tolerance for specific homemaking or vocational activities (145–147). To accomplish these objectives, the multidisciplinary team must use many skills. In many cases, the patient with chronic pain is so entrenched in pain behavior that a behavior modification approach is essential. These patients are often characterized by low levels of activities of daily living, high demand for medication accompanied by physical and psychological dependency, high verbalization of pain, and the inability to work.

### Pain Treatment Centers

The organization and operation of the multidisciplinary pain clinic has been discussed by multiple authors (148,149). Many behavior modification programs use the Fordyce model (69,88). This approach uses the general principles of interruption of the pain behavior reinforcement cycle, reward of healthy behavior, appropriate goals that the patient must achieve, measurement of improvement by functional assessment, as well as pain level, and psychosocial adjustment. Particular emphasis is placed on detoxification and medication reduction, pain reduction, increased activity, and modification of pain behavior.

If the patient is on pain medications and determined to be physically or psychologically dependent, he or she must be detoxified. This is routinely accomplished by establishing the equivalent dosage of each medication type (e.g., opioids, benzodiazepines, barbiturates, alcohol). Opioid medications are replaced with methadone, and long-acting barbiturates are replaced with phenobarbital or pentobarbital. Medication equivalents are placed in orange juice or in capsulated form and decreased at a rate of 5% to 10% per day. The medication is then given on an around-the-clock basis at fixed intervals. Gradual reduction of the pain ingredients occurs without significant side effects of withdrawal. The patient is not aware of the timing of the decrease but has been informed of the concept before starting the program. Nonsteroidal anti-inflammatory drugs (NSAIDs) and tricyclic or selective serotonin reuptake inhibitor (SSRI) antidepressants are routinely integrated as long-term medications. The pain management program is designed to reduce rather than eliminate pain, while increasing the patient's functional capabilities.

The patient with chronic pain usually exhibits a decreased activity level, which results in a disuse syndrome. The exercise programs are based on the initial specific and general exercise that the individual can perform. The exercise regimen is progressive, with the goals rising along with the patient's ability. Rewards for accomplishing tasks are a mainstay of this program with no reinforcement given for pain behavior. The achievable goals provide success and confidence and allow for frequent

reinforcement when they are met. Cooperation by all staff members is essential; they must consistently ignore reports of pain and encourage improved function. Psychological intervention is used as indicated. The chronic pain behavior modification programs report short-term success rates in medication reduction, increased activity, and more productive behavior patterns (150,151). Statistics suggest improvement of 60% to 80% in patients with chronic pain without major psychosocial components, 30% to 50% in patients with significant psychosocial components, and approximately 20% in patients with major psychiatric components or secondary gains (148,152–156).

Multidisciplinary chronic pain treatment is a focused, unified approach to the chronic pain syndrome. In the United States, pain treatment centers differ widely in organization and emphasis. They are generally multidisciplinary centers that use some combination of anesthesiologists, clinical psychologists, dentists, neurologists, orthopedists, pharmacists, physiatrists, and psychiatrists. The goals of these centers are to diminish, if not eliminate, chronic pain; increase the patient's functional capabilities to allow for a more active life; and decrease the patient's dependence on drugs for pain control (Table 49-4).

### Physical Modalities

Physical modalities are valuable adjuncts in the successful management of acute and chronic pain. Therapeutic heat and cryotherapy are time-honored interventions in the treatment of painful musculoskeletal conditions. Clinical evaluations of transcutaneous electrical nerve stimulation (TENS), acupuncture, and cold laser have questioned the efficacy of these methods in alleviating discomfort (157–161). For additional information on physical agents, the reader is referred to Chapter 63.

Pain arising from the musculoskeletal system is often caused by muscle spasm (127). Heat and cold applications are primarily directed at reducing spasmodic muscle shortening. The shortened muscle may be a result of direct muscular trauma or underlying primary neurologic or skeletal disease. Investigators have studied the muscle spindle and its firing rate in relation to thermal changes (162,163). Direct and indirect effects on the muscle spindle are detected from both heat and cold applications (164). The return of the muscle to its normal resting length is also believed to promote the reduction and resolution of pain (165), but precisely how muscle spasm is relieved is not completely understood.

Physical modalities should be used with caution and to a limited extent. Passive treatment programs such as hot packs, massage, and ultrasound may be appropriate for a short period of time; however, an active treatment program should be implemented as early as possible. The patient should be transitioned to a home program involving exercise, stretching, and self-applied modalities as early as possible. Additional outcome studies have demonstrated the effectiveness of therapeutic exercise for chronic back pain patients. Unfortunately, there remains limited consensus regarding the most effective exercise programs for patients with low back pain (166–169).

**TABLE 49.4 Step 1: Nonopioid Analgesics for Mild to Moderate Pain**

Drug	Plasma Half-life (h)	Peak Effect (h)	Duration of Analgesia (h)	Usual Dose (mg) <sup>a</sup>	Maximum Recommended Dose (mg/d) <sup>b</sup>	Comments
Aspirin	4–16	1–2	4–6	650 q 4–6 h	6,000	Standard of comparison for non-opioids; irreversible effect on platelet aggregation
Acetaminophen	1–4	3	1–4	650 q 4–6 h	4,000	No effect on gastric mucosa, platelet aggregation, or anti-inflammatory response.
Diclofenac	6–8	2–4	10–12	50–75 q 12 h	150	Hepatotoxic >4 g/d
Diffunisal	8–12	2–3	8–12	500 q 12 h	1,500	Decreased GI toxicity
Indomethacin	4–5	1–2	4	25–50 q 8 h	200	No effect on platelet aggregation with <1 g/d, decreased GI toxicity
Ibuprofen	2–4	1–2	4–6	400–800 q 8 h	2,400	Not routinely used because of greater incidence of GI toxicity and CNS side effects
Flurbiprofen	5–6	2–4	4–6	50 q 4–6 h	300	Rapid onset of action. Side effects include nephrotoxicity, tinnitus, CNS, and cardiovascular problems
Naproxen	12–17	2–3	8–12	250–500 q 12 h	1,500	No effect on platelet aggregation.
Piroxicam	45–50	3–5	12	20 q 24 h	40	Decreased GI toxicity <20%
Salsalate	4–16	1–2	4–12	1,000 q 8 h	4,000	Available in liquid suspension
Sulindac	14–16	3–4	8–12	150 q 12 h	400	Not recommended with liver or kidney dysfunction. Higher incidence of side effects at a dosage of 40 mg qd over 3 wk
Nabumetone	20–30	1–2	8–12	500 q 12 h	2,000	No effect on platelet aggregation.
Choline magnesium trisalicylate	4–6	3–5	4–12	1,000–1,500 q 12 h	4,000	Low GI toxicity
<i>Cox II inhibitors</i>						Decreased renal toxicity
Celebrex (celecoxib)	11–13	2–9	8–12	200 q 12 h	800	Near placebo level, GI side effects (4%)
<i>Atypical analgesic</i>						No effect on platelet aggregation.
Tramadol	4.5–7.5	1–4	6–8	50 q 6 h	800	Low GI toxicity
						Atypical central acting analgesic <sup>c</sup>
						Risk of seizure, low GI toxicity

CNS, central nervous system; GI, gastrointestinal; NSAIDs, nonsteroidal anti-inflammatory drugs; q 12 h, every 12 h (etc.).

The authors will not assume liability for this table. No medication should be given until the complete prescribing recommendations, drug use indications, and potential side effects that are listed in the package insert with the product or contained in a drug reference manual are reviewed and understood thoroughly by the physician and patient. Drug dosages may need to be modified for the elderly.

<sup>a</sup>Dosage should be adjusted in elderly patients, patients on multiple medications, and patients with renal insufficiency or hepatic failure. Doses may be increased at weekly intervals if pain relief is inadequate and dosage is tolerated. Doses and intervals titrated to effect.

<sup>b</sup>The patient should be evaluated routinely for hepatic toxicity. Patients receiving NSAIDs also should be evaluated for renal toxicity and fecal blood loss that is due to gastrointestinal irritation. It is recommended that patients who develop visual symptoms during treatment undergo ophthalmic evaluation. Gastrointestinal disturbance may be reduced if taken with milk, on a full stomach, or with antacids.

<sup>c</sup>Combined action as an opioid agonist and monaminergic drug with potential abuse potential. Nausea and vomiting side effects at same rate as opioid medications. Classified by World Health Organization as weak opioid, however classified in United States as nonopioid medication. Serious potential consequences of overdose are central nervous system depression, respiratory depression and death. 100 mg PO tramadol approximately equivalent 30 mg PO morphine. GI disturbance reduced with misoprostol 200 mg q 6 h. Misoprostol or a proton pump inhibitor is recommended in patients who are at increased risk for upper gastrointestinal adverse events. Max dose 1,600 mg/d. Do not give to pregnant women.

### Cryotherapy

Therapeutic cold has four distinct applications in medicine: stop or slow bleeding, induce hypothermia, decrease spasticity, and relieve pain (170,171). It may be applied as a solid, liquid, or gas. Ice is a common, solid form of direct cold therapy and is usually rubbed in a circular fashion over the localized painful area. Immersing a body part in water combined with ice chips may also provide pain relief. Cold applied directly to an injured area in acute musculoskeletal trauma serves to reduce hemorrhage and vasodilation, blunts the local inflammatory response, decreases edema production, and reduces pain perception. The so-called PRICE (protection, rest, ice, compression, and elevation) method is commonly prescribed for acute sports-related injuries (172).

In addition to acute musculoskeletal injuries, cryotherapy has been shown to benefit chronic painful conditions. Pain may be alleviated by direct or indirect mechanisms (173). Direct cold application serves to decrease temperature in the affected area. Reduced pain sensation is presumed to result through an indirect effect on the nerve fibers and sensory end organs. Additionally, the lowered temperature reduces muscle spindle firing rate and decreases the painful muscle tone (163,173).

The direct application of ice massage has been shown to be therapeutically efficacious in several clinical trials. Grant demonstrated the beneficial effects of direct ice application on a large population of young individuals sustaining acute and chronic musculoskeletal trauma (174). Pegg and colleagues demonstrated that chronic, inflammatory joint disease improved with cold application with regard to pain, stiffness, and range of motion (175). Patients with low back pain also responded well to controlled clinical trials using cryotherapy (176,177).

The application of cold as a vapocoolant spray was popularized by Travell in treating myofascial pain syndromes (178). A counterirritant effect is presumed to provide the mechanism of muscle spasm relief and pain alleviation. The combination of vapocoolant spray, stretching, and trigger point injection has been reported to provide significant pain relief in myofascial pain syndromes (179,180). The mechanism of this pain relief remains unclear.

Adverse effects also have been reported with the use of cold (173). The major adverse reaction is hypersensitivity. Patients with Raynaud's and peripheral vascular disease should not have their limbs exposed to cold temperatures because this produces vasoconstriction. Additionally, patients who display a marked cold pressor response are poor candidates for cryotherapy. Care should be taken not to apply ice for a sustained period of time over the medial elbow or the head of the fibula as this may result in cold-induced injury to the ulnar and peroneal nerves, respectively. When applying an ice bag to a large joint or limb, a patient should be advised to place a towel between the ice and their skin and to limit their exposure to 20 minutes.

### Heat Therapy

Heat application is a common form of pain treatment. It is generally accepted that therapeutic heat is best tolerated in the subacute and chronic phases of a disease process. The physiologic responses produced by heat are increased collagen

extensibility, increased blood flow and metabolic rate, and inflammation resolution. Decreased joint stiffness, muscle spasm, and pain are also beneficial effects of heat.

Therapeutic heat is believed to have direct and indirect effects on the muscle spindle. Local elevated temperatures have been shown to directly decrease the spindle sensitivity (181), and superficial heating of the skin has been demonstrated to indirectly reduce spindle excitability (164). This mechanism is similar to that proposed for decreased muscle spindle activity with the application of cold. It is also believed that the pain threshold may be raised by the direct and indirect actions of heat.

Pain associated with numerous conditions has been successfully treated with therapeutic heat application (182). Musculoskeletal contractures respond well to deep heat used in association with prolonged stretch (183). Joint stiffness associated with chronic inflammatory diseases, particularly those affecting the limbs, responds to superficial heating with decreased pain and increased range of motion and function. Subacute and chronic bursitis, tenosynovitis, and epicondylitis also may respond to heat with decreased pain and symptom resolution (177).

Contraindications to superficial heat include sensory impairments, circulatory insufficiency, malignancy, and infection. Edema is considered a relative contraindication with the benefits of the treatment weighed against the potential disadvantages. Contraindications for the use of ultrasound include use over the eye, malignancy, impaired circulation, pregnancy, impaired sensation, and infection. Contraindications for other deep-heating modalities include pregnancy, ischemic tissue, pain or sensory deficit, areas of high fluid volume, and any metal implants.

### Transcutaneous Electrical Nerve Stimulation Therapy

The use of electrical currents dates back to the Greeks, who applied torpedo fish to individuals suffering from pain (184). Therapeutic electricity eventually fell into disrepute until Melzack and Wall proposed the gate control theory of pain (36). This gate control model provided the theoretical basis for the use of electrical current in pain control. They found that the preferential activation of large afferent fibers using TENS would inhibit the transmission of painful impulses. The exact physiologic basis by which TENS produces pain control is unknown.

TENS also has been used extensively to manage chronic pain. The results have been less promising and more variable than those in acute pain trials (185,186). Rigorous controlled trials suggest that TENS is no better than placebo in the management of chronic low back pain (3,158,187). Patients with CRPS, phantom limb pain, and peripheral nerve injury have demonstrated pain control with TENS (188–190). The most efficacious use of TENS appears to be in the control of selected acute pain conditions, such as postoperative incisional pain.

There are relatively few side effects related to TENS. The major problem is one of skin irritation related to the conducting paste or tape used to secure the electrodes. The use of TENS in patients with demand cardiac pacemakers is inadvisable (190).

## Acupuncture

Acupuncture (originating from the Latin *acus* or “sharp point” and *punctura*, “to puncture”) is an ancient Chinese therapy practiced for more than 2,500 years to cure disease or relieve pain. Thin, solid metal needles are inserted into specific body sites and slowly twisted manually or stimulated electrically. Various sensations may be produced, ranging from a dull ache or warmth to that of a pinprick. The Chinese believe that acupuncture achieves its beneficial results by restoring the balance between *yin* (blood) and *yang* (spirit), which flow in 14 channels or meridians containing 361 acupuncture sites.

Researchers have considered acupuncture to be a form of neuromodulation. Two theories have been proposed for its use in pain control. First, acupuncture may stimulate large sensory afferent fibers and suppress pain perception as explained by the gate control theory of pain. Second, the needle insertion may act as a noxious stimulus and induce endogenous production of opioid-like substances to effect pain control (190).

It has been demonstrated that there is a significant overlap between traditional acupuncture sites, myofascial trigger points, and muscular motor points (191). The sensation induced by the application of an acupuncture needle is very similar to the dull ache often experienced by the patient when a trigger point is injected. The insertion of a needle, regardless of the substance injected, appears to produce the beneficial pain relief and is termed the *needle effect*. The injection of trigger points may share not only similar areas of needle insertion, but also associated mechanisms of pain control.

Acupuncture has been used in a wide variety of painful conditions (192,193). The insertion of a needle is considered an invasive procedure, and many states require a physician to perform or supervise the treatment. Uniform agreement does not yet exist as to the preferred time necessary for an adequate trial of acupuncture. There is limited evidence to suggest that acupuncture is more effective than placebo or sham acupuncture for chronic low back pain in the short term only. There is no evidence that acupuncture is more effective than other treatments such as NSAIDs. While acupuncture may be a useful adjunctive treatment in pain management, more high-quality studies are needed to confirm its efficacy and guide its use (159,160,194,195).

Reported side effects of acupuncture include localized hyperemia occurring frequently following needle insertion. Infrequently, syncopal episodes, hematoma formation, and pneumothorax also have been reported. Caution is suggested in the use of electrical acupuncture with patients who have cardiac pacemakers (196).

## Therapeutic Exercise

During acute injuries to the musculoskeletal system, a muscle may shorten as a protective reaction to pain. Treatment typically consists of immobilization combined with compression and cryotherapy. As the pain subsides, mobility is restored gradually. If normal range of motion is not achieved, the muscle may become chronically shortened and result in additional pain.

Prolonged muscle shortening will add to the painful condition by producing contracted soft-tissue structures. In the

chronic phase of pain, the optimal treatment methodology combines graded stretching movements, strengthening exercises, heat or cold, and massage. The patient is also educated regarding proper body mechanics and the need to continue the prescribed therapeutic exercise regimen outside of formal therapy sessions.

Therapeutic exercise, prescribed to correct a specific abnormal condition, is often used to treat chronic painful conditions. The primary goal is to aid the patient in achieving pain control. This may be accomplished through the restoration of normal muscle tone, length, strength, and optimal joint range of motion (197). Finally, the patient is urged to continue a home program after formal therapy sessions have ceased (121).

Therapeutic exercise consists of passive movements, active-assistive exercises, active exercises, stretching, and relaxing exercises. Each may be used alone or in combination to achieve the desired effect (153,198–202). In the case of low back pain, there has been disagreement as to which exercise program is most effective in the treatment of chronic, low back pain. One school of thought is that therapeutic stretching exercises, similar to the YMCA program developed by Kraus, are effective in the management of chronic low back pain (3,121,167,169). A recent meta-analysis of randomized, controlled trials in patients with low back pain showed a positive effect in function both immediately and at follow up. While this study highlighted the variety of programs that are incorporated under the umbrella of “exercise,” the majority (12 out of 16) incorporated an element of strengthening (202). There is an emerging school of thought that the maintenance of lumbar spinal stability over time can limit the pain associated with degenerative disc disease and spondylosis.

This stability is thought to be secondary to three components: the bones and ligaments of the spine, the muscles, and the nerves that coordinate muscle activation (203). The muscles are the major stabilizers, specifically the multifidi, the transversus abdominis, the pelvic floor muscles, and the diaphragm (204). Without the assistance of the muscles and their nerves, a cadaver spine with bones and ligaments intact will buckle and collapse under a load of 20 lb (205).

The multifidi are rich in muscle spindles; therefore, they act to both stabilize individual segments of the spine and to provide proprioceptive feedback of spinal movement. There is some evidence that these muscles may be atrophied in patients with low back pain (206).

The other muscles, including the transversus abdominis, form a muscular cylinder that increases intra-abdominal pressure also effectively stabilizing the spine. The transversus abdominis is one of the first muscles to be activated to stabilize the spine; however, studies have suggested that its activation may be delayed in patients with back pain (207,208).

Several small studies have shown a promising effect of lumbar stabilization programs targeted at strengthening the above, deep muscles in treating a number of painful and potentially destabilizing spinal conditions. Of note, O’Sullivan and colleagues reported a significant improvement in pain and function of a group of patients with spondylolysis and spondylolisthesis treated with lumbar stabilization compared

to patients treated with general exercise (209). In a study by Cairns (210), 95 patients with recurrent back pain were randomized into treatment with “conventional physical therapy” involving general active exercise or a program including specific strengthening of the spinal stabilizers. Both groups improved, but there was no statistically significant difference in function between the two groups on follow up.

Passive forms of therapeutic exercise (mobilization, manipulation, and massage) have not been shown to be superior to other routine treatments (general practitioner care, analgesics, home exercises, or back school) in the management of neck and back pain (211–215). For additional information on therapeutic exercise, the reader is referred to Chapter 61.

### Behavioral Treatment Modalities

Among the treatment goals of pain management are the decrease in illness behavior (reduced drug use and visits to physicians) and the increase in well behavior (increased physical activities, mobility, and return to gainful employment). This may be accomplished by blocking noxious sensory input, decreasing tension and depression, rearranging reinforcement contingencies, or assisting in the learning of new behaviors (216). Biofeedback, cognitive behavior modification, operant approaches, hypnosis, operant pain hypnosis, and relaxation training can assist in the treatment of chronic pain behavior (217–222,222a).

Biofeedback has found some use in the treatment of chronic pain (223–225). Typically, biofeedback teaches muscle relaxation (through surface EMG) or temperature control. The instrumentation is reported to be somewhat useful, although clinical experience suggests that relaxation without instrumentation is of equal value. Through biofeedback training, the patient learns self-regulation of pain.

Cognitive behavior modification (220) helps the patient learn self-coping statements and problem-solving cognitions (226) in order to alter the cognitive structures (schemata, beliefs) and cognitive process (automatic thoughts, images, and internal dialogue) associated with the pain experience. Cognitive strategies of imaginative inattention, imaginative transformation of pain, focused attention, and somatization in a dissociation manner have been found helpful.

The operant approach involves the identification of behaviors to be produced, increased, maintained, or eliminated. Reinforcement is then regulated to achieve the desired outcome. Activity and walking programs are followed to the prescribed level, not to discomfort. All medication is prescribed by schedule. Family and friends are instructed to avoid reinforcing all pain behavior.

Relaxation methods (227,228) to reduce tension may include deep muscle relaxation, deep diaphragmatic breathing, meditation, yoga, and autogenic training. Patients also may be taught self-hypnosis (223). Hypnosis (229–233) has the advantage of providing pain relief without unpleasant side effects, no reduction in normal function, and no development of tolerance. Hypnotic strategies can suggest analgesia or anesthesia, substitute another feeling for pain, move the pain perception to a smaller or less vulnerable area, alter the meaning of pain,

increase tolerance to pain, or, in some individuals, dissociate the perception of body from the patient’s awareness.

### Pharmacologic Intervention

Two groups of patients are encountered in the clinical management of chronic pain. The first group includes individuals with recurrent, overlying acute exacerbations of pain due to flares of chronic medical illness, such as rheumatoid arthritis, cancer, and burn injuries. Primary therapy is usually directed at the underlying cause of pain. When the therapy is successful, the pain treatment is successful, and the patient can return to their baseline level of pain (if any). Treatment commonly includes NSAIDs. Opioid analgesics are used on time-limited regimes to minimize the development of psychological dependence. The second group of patients consists of individuals who have chronic pain without apparent organic etiology. Pharmacologic intervention is the most common means of treatment for all forms of chronic pain. Pharmacological substances may be divided into three categories: nonopioids, opioids, and adjuvant drugs.

#### Nonopioid Analgesics

Nonopioid medications are primarily NSAIDs that include aspirin, acetaminophen, and simple NSAIDs (see Table 49-4). These drugs are peripherally active analgesics that do not inhibit nociception or alter the perception of the pain input. They are best considered remittent agents that alter the pathologic processes that generate pain. Aspirin and other NSAIDs reduce pain by interfering with prostaglandin sensitization of nociceptors and inhibiting the synthesis of prostaglandins. Additional NSAID actions include inhibition of tissue reaction to bradykinin, suppressed release of histamine, and decreased vascular permeability. This improves the environment of the nociceptor, increasing pain control by decreasing sensitivity. With the exception of acetaminophen, the NSAIDs also possess anti-inflammatory effects that reduce local heat, swelling, and stiffness. These drugs are used to treat patients with acute and chronic pain of low to moderate severity.

NSAIDs are often chosen over opioids because they have fewer side effects, including no constipation, very little sedation, no psychological or physical dependence, and no development of tolerance. The mainstays of nonopioid analgesic therapy are aspirin and acetaminophen. Acetaminophen is an excellent alternative to aspirin in patients who are unable to tolerate other NSAID medication. All NSAIDs have ceiling effects, but the ceilings for some of these drugs are higher than that of aspirin (234).

Although aspirin, acetaminophen, and other NSAID compounds are available over the counter, they all have potential side effects. The most common complication, involving the gastrointestinal tract, is seen in 5% to 10% of patients. These drugs produce in varying degrees gastrointestinal, hematologic, renal, and hepatic toxicities. The side effects from prolonged use of all NSAIDs are similar to those occurring with aspirin, but there are significant differences in the potential for side effects. Aspirin, in the nonsalicylated salsalate form, remains the preferred drug for the patient with chronic pain.

The newer NSAIDs have not been proven to offer any major advantage over aspirin, although their cost is much greater (121,167,235–238). Notable exceptions to this are patients unable to tolerate acetylsalicylic acid or who demonstrate difficulty with compliance. For additional information on NSAID medications, the reader is referred to Chapter 66.

### Opioid Analgesics

Opioid medication is useful and appropriate in the treatment of acute, recurrent, or cancer pain. Acute and recurrent pain are usually best managed by diagnosis and treatment of the underlying cause of the pain. The opioid medication is used as an adjunct to provide relief during a period of temporary, excruciating pain. Opioid analgesics are also preferred for relief of intractable pain that is due to cancer. The greatest obstacle to treating postoperative pain, pain related to cancer, acute pain, and recurrent pain that is due to chronic disease is the excessive concern of the physician regarding addiction. Repeated studies report that a high percentage of clinicians tend to overestimate their patient's potential for addiction and, consequently, undermedicate them (83–85,239). Ironically, undermedication may increase the potential for addiction as a result of the

operant conditioning, anxiety, and dependent behavior created by inadequate pain relief. Psychological dependence has not been a major problem in patients with acute pain or cancer pain who receive appropriately dosed opioid analgesics for moderate to severe pain (240,241).

Opioid medications should be avoided in the treatment of patients with chronic pain without active organic etiology. There is limited justification for the use of opioid drugs in a patient without an organic etiology for chronic pain (242). Long-term use of opioid drugs with these patients often produces behavioral complications that are more difficult to manage than the initial pain problem. The hazards of tolerance, physical dependence, and psychological dependence present major problems in the long-term management of this patient group. Deficits of cognition and motor function, as well as the masking of psychological disorders, are common. Immune suppression, hormonal axis suppression, and hyperalgesia are also possible (44). The indiscriminate use of opioid medications in an attempt to control chronic pain only enhances chronic pain behavior. For patients with pain secondary to organic etiology, tolerance and dependence are expected with long-term use of opioids and do not equal addiction (Table 49-5).

**TABLE 49.5 Step 2: Opioid Analgesics for Moderate Pain**

Drug	Equianalgesic Dosage (mg)			Action Time <sup>a</sup> (h)			Usual Dose Limits (mg)	Comments <sup>e</sup>
	Aspirin Orally <sup>b</sup>	Morphine IM <sup>c</sup>	Morphine Orally <sup>c,d</sup>	Half-Life	Peak Effect	Duration of Analgesic		
Codeine	32	120	200	2–3	1–2	3–6	32–65 q 3–4 h	Weak, short acting; as dose increases, nausea, vomiting, and constipation occur more frequently.
Hydrocodone	2.5	15	30	2–4	1–2	3–6	5–10 q 3–4 h	Only available combined with NSAIDs.
Meperidine	50	90	300	2–4	1–2	3–6	50–100 q 3–4 h	Not recommended for the treatment of cancer pain.
Oxycodone	2.5	15	20–30	2–4	½–1	3–6	5–10 q 4–6 h	Fast acting. Combined with NSAIDs.
Pentazocine	30	60	180	2–3	½–1	2–3	50–100 q 4 h	Not recommended for the treatment of cancer pain.
Propoxyphene	100–200		300	2–3	1–2	3–6	100–200 q 4 h	Not recommended for the treatment of cancer pain.

IM, intramuscularly; NSAIDs, nonsteroidal anti-inflammatory drugs; q 4 h, every 4 h (etc.).

The authors will not assume liability for this table. No medication should be given until the complete prescribing recommendations, drug use indications, and potential side effects that are listed in the package insert with the product or contained in a drug reference manual are reviewed and understood thoroughly by the physician and patient. Drug dosages may need to be modified for the elderly.

<sup>a</sup>Varies with route of administration.

<sup>b</sup>Dose providing analgesic equivalent to 650 mg aspirin orally.

<sup>c</sup>Dose providing analgesic equivalent to a single dose of 10 mg morphine IM, intravenous, or subcutaneous.

<sup>d</sup>Relative potency of IM morphine to oral morphine is 1:6 with acute dosing and is 1:2–3 with chronic dosing.

<sup>e</sup>Most common side effects of opioid drugs include constipation, nausea, and sedation. Less common side effects include urinary retention, bladder spasm, respiratory depression, and intermittent vomiting. Rare side effects include psychotic symptoms, pruritis, orthostatic hypotension, bronchoconstriction, and biliary colic. The dosage should be adjusted in elderly patients and patients with impaired ventilation, increased intracranial pressure, liver failure, or bronchial asthma.

It is often necessary to educate the patient and family regarding the appropriate use of opioids for pain that is due to organic etiology. For additional information on opioids, the reader is referred to Chapter 66.

Morphine is the opiate drug prototype and commonly prescribed by many clinicians (8,237). Pain relief is often obtained by titrating the dose to the patient's needs. At equianalgesic doses, there is no significant pharmacologic evidence to suggest the efficacy of one opioid over another (243,244), but there are significant differences in their action times, equianalgesic dose, and parenteral/oral ratio (Table 49-6). Inappropriate drug dosing often occurs because of a lack of knowledge or attention to equianalgesic doses, resulting in inadequate pain relief.

All clinically useful opioids produce similar side effects in equianalgesic doses. The undesirable side effects of opioids include respiratory depression, unwanted sedation, mental clouding, inability to concentrate, lethargy, impairment of mental and physical performance, constipation, nausea and

vomiting, tolerance, physical dependence, and psychological dependence. These side effects compromise a patient's main goal of maintaining a normal lifestyle. When introducing opioid medications for the first time or changing a patient's chronic dosage, it is imperative to counsel them about precautions regarding increased sedation, driving impairment, risk of falls, and risk of respiratory depression over the next days to weeks until the patient becomes acclimated.

Oral administration of medication is preferred in the treatment of all pain. A time-contingent, round-the-clock schedule for pain medications is superior to an as-needed schedule. This form of administration minimizes alterations in plasma levels and provides optimal pain control. The schedule should be based on such variables as potency, duration of the analgesic effect, and efficacy of the analgesic medication. A regularly scheduled dosage optimizes the reduction of pain by minimizing the peaks and valleys of pain intensity. Generally, it is better to begin the initial dose of medication too high rather than

**TABLE 49.6 Step 3: Opioid Analgesics for Severe Pain**

Drug	Equianalgesic Dosage (mg) <sup>a</sup>			Action Time <sup>b</sup> (h)			Usual Dose Limits (mg) <sup>d</sup>	Comments <sup>e</sup>
	IM	Orally <sup>c</sup>	IV	Half-Life	Peak Effect	Duration of Analgesic		
Hydromorphone	3	7.5	3	2–3	½–1½	2–4	4–8 q 3–4 h	Fast acting
Levorphanol	2	4	1	12–16	1–2	4–5	2–4 q 4–6 h <sup>f</sup>	Increased sedation with repeated doses
Methadone <sup>h</sup>	10	20	—	15–57	1–2	6–8	15 q 8 h	Avoid in patients with significant respiratory, hepatic, cardiac, or renal failure
Fentanyl transdermal patch	—	—	—	16–24	12–24	58–72	100 µg/h patch q 48 h	Usually not recommended for opioid naïve patients
Morphine	10	30g	5	2–4	½–1½	3–6	10 q 4 h	Standard of comparison for opioids
Sustained-released morphine	—	30g	—	2–4	—	8–12	60 mg q 12 h <sup>g</sup>	
Oxymorphone	1	—	0.5	2–3	30–90	4–6	10 q 4 h	Rectal suppository <sup>i</sup>

IM, intramuscularly; IV, intravenous; q 4 h, every 4 h (etc.); q 3 d, every 3 d.

The authors will not assume liability for this table. No medication should be given until the complete prescribing recommendations, drug use indications, and potential side effects that are listed in the package insert with the product or contained in a drug reference manual are reviewed and understood thoroughly by the physician and patient. Drug dosages may need to be modified for the elderly.

<sup>a</sup>Dose providing analgesic equivalent to a single dose of 10 mg morphine IM, IV, or subcutaneous.

<sup>b</sup>Varies with route of administration.

<sup>c</sup>Relative potency of IM morphine to oral morphine is 1:6 with acute dosing and is 1:2–3 with chronic dosing.

<sup>d</sup>Dosage varies considerable, titrate to control pain.

<sup>e</sup>Most common side effects of opioid drugs include constipation, nausea, and sedation. Less common side effects include urinary retention, bladder spasm, respiratory depression, and intermittent vomiting. Rare side effects include psychotic symptoms, pruritis, orthostatic hypotension, bronchoconstriction, and biliary colic. The dosage should be adjusted in elderly patients and patients with impaired ventilation, increased intracranial pressure, liver failure, or bronchial asthma.

<sup>f</sup>For chronic dosing only. For single dose use 1.5 mg.

<sup>g</sup>For chronic dosing only. For single dose use 60 mg.

<sup>h</sup>Dosage conversion with methadone is nonlinear and highly variable half-life results in potential for accumulation. Caution is recommended. May result in prolonged QT interval in at risk patients. Consult methadone conversion table or pain specialist.

<sup>i</sup>10 mg rectal equianalgesic to 10 mg morphine IM.

too low. Starting suboptimally and titrating upward results in the patient's experiencing pain and anxiety because of a lack of adequate analgesic. The as-needed, or "prn," schedule does not have a place in the control of chronic pain. Such a schedule results in operant conditioning, craving, a sense of dependence, and anxiety about the drug wearing off. The administration of opioids before the recurrence of pain sensation decreases the development of central nervous system sensitization. In chronic pain management, the drugs with longer duration of action are usually preferred. There is considerable patient-to-patient variation with respect to effective analgesic dosage; therefore, it is important to individualize the medication regime for each patient (245,246).

Titration of opioids is generally accomplished by increasing or decreasing the next dose by one fourth or one half of the previous dose. During titration, patients are often provided with medication for breakthrough pain. Rapidly acting opioids of approximately 10% of the individual's baseline opioid equianalgesic dose may be given every 2 to 3 hours as needed (247,248).

### Adjuvant Analgesic Medications

The adjuvant analgesic drugs produce or potentiate analgesia by mechanisms not directly mediated through the opiate receptor system (Table 49-7). This group includes a wide variety of compounds with no proven specific analgesic properties: antidepressants, anticonvulsants, and antispasmodics. The use of these drugs is often based on anecdotal data, clinical surveys, or limited drug trials.

SSRIs are often used to manage the psychological factors common to chronic pain syndromes. These medications have not been shown to have direct analgesic properties, and their mechanism of action is unclear. SSRIs such as citalopram, fluoxetine, fluvoxamine, paroxetine, desvenlafaxine, and sertraline have few serious side effects but have been noted to cause insomnia, memory impairment, and weight changes. SSRIs are used for multiple pain conditions (249–252). SNRIs, such as duloxetine and venlafaxine, are also now used in treatment of neuropathic pain and depression (253,254).

Tricyclic antidepressants, such as amitriptyline, doxepin, and imipramine, have been used in the treatment of chronic pain syndromes. One of the primary mechanisms of tricyclic compounds is to block the reuptake of the neurotransmitter serotonin in the central nervous system. This enhances pain inhibition by way of the dorsolateral pathway (32,255). In addition, amitriptyline is a potent sedative drug, which may be used as a sleeping medication in patients with chronic pain. The combination of antidepressant effect, enhanced cortical serotonergic mechanism, and improved sleep contributes to these medications being one of the most commonly used group of psychotropic agents in pain management (256–258).

Gabapentin, pregabalin, and other antiepileptic drugs are used in the management of pain syndromes affecting the central nervous system. Anticonvulsants such as pregabalin, gabapentin, lamotrigine, levetiracetam, oxcarbazepine, tiagabine, topiramate, and zonisamide have the advantage of a much-improved side-effect profile compared with carbamazepine, phenytoin, and

valproic acid. Their applications include trigeminal neuralgia, postherpetic neuralgia, causalgia, phantom pain syndromes, painful diabetic neuropathy, and FM (259–262). Although the mechanism is unclear, they appear to have a stabilizing effect on excitable cell membranes, which decreases afferent and efferent second-order neuron activity (263–267).

Alternative anticonvulsants used for pain control are valproic acid and clonazepam. They increase the effectiveness of GABA-induced inhibition in the pre- and postsynaptic systems. These drugs appear to be most effective in the treatment of neuralgias and neuropathies. Antispasmodics such as baclofen are presumed to act by inhibiting gamma transaminases and their reuptake at gamma receptor sites. Valproic acid and clonazepam act in a similar fashion (268–270).

In addition to these medications, a number of other adjuvant medications have been used. These include methotrimeprazine, chlorpromazine, and fluphenazine. Butyrophenones are anecdotal in the management of pain disorders, with haloperidol being the most often reported. Antihistamines, amphetamines, steroids, and cannabinoids are also reported anecdotally. Steroids such as prednisone and dexamethasone are thought to interfere with prostaglandin sensitization of nociceptors. Serotonin antagonists such as ergot alkaloids, the  $\beta$ -blocking agents such as propranolol, and the antihistamines such as hydroxyzine all function by antagonizing transmitters that directly activate nociceptors. These medications have been used extensively in the treatment of migraine and cluster headaches. Lithium and calcium-blocking agents have been proposed as drugs to interfere with the release of transmitters involved in the pain process (41).

Benzodiazepines and barbiturates are two groups that have little or no place as adjuvant drugs in chronic pain management. Long-term use of these medications may result in psychological and physical dependence as well as in interference with cognition and motor function. Historically, benzodiazepines, because of their claimed muscle relaxant properties, are often prescribed to patients with pain. However, their role as muscle relaxants is questionable in clinical studies (271–273). In addition to the adverse effects of dependency, it has been suggested that these medications adversely affect the serotonin system. These medications are depressants that, with long-term use, lower pain tolerance, increase hostility, and tend to induce clinical depression as well as psychological and physical dependence (274,275). Because of their sedative effects, depressants often act as potent reinforcers of pain in drug-seeking behaviors. Chronic use of these medications may result in physical and mental incapacitation, emotional instability, and the inability to deal with initial physiologic or psychological problems. Benzodiazepines deplete serotonin, alter sleep patterns, and increase pain perception. It is recommended that these two groups of medications should not be part of the long-term management of chronic pain. The only possible indication for these sedatives, or for antianxiety agents, is for the short-term (<1 month) treatment of a self-limited crisis unrelated to the particular pain problem, or as an adjunct when detoxifying a patient from opioid medication.

**TABLE 49.7** Adjuvant Analgesic Medications

Drug Class	Drug	Indication	Usual Dose <sup>a</sup>	Maximum Dose (mg/d)	Comments
Antidepressants	Amitriptyline	For neuropathic deafferentation, and somatic pain complicated by insomnia or depression.	25–75 mg qhs or divided dose	300 mg/d	Tertiary amines—sedative, if morning somnolence is a problem, give dose earlier in the evening Secondary amines—less sedative Selective serotonin and norepinephrine reuptake inhibitor (SSNRI) Selective serotonin reuptake inhibitor (SSRI)
	Doxepin			50 mg/d	
	Imipramine		25 mg tid-qid	300 mg/d	
	Clomipramine		50–200 mg qd	375 mg/d	
	Nortriptyline		37.5 mg bid	60 mg/d	
	Desipramine		20 mg qam	80 mg/d	
	Venlafaxine		20 mg qam	200 mg/d	
	Duloxetine		30 mg bid	60 mg bid	
	Citalopam		50 mg qam	3,600 mg/d	
	Fluoxetine		300 mg qid	1,800 mg/d	
	Sertaline		200 mg bid	200 mg/d	
Anticonvulsants	Pregabalin	Intermittent lancinating and continuous neuropathic pain	50 mg tid	450 mg/d	Few side effects, few drug-drug interactions Risk of leucopenia
	Gabapentin		300 mg qid	3,600 mg/d	
	Topiramate		50 mg bid	1,800 mg/d	
	Phenytoin	Lancinating pain	100 mg tid	600 mg/d	
	Lamotrigine		50 mg bid	400 mg/d	
	Carbamazepine		200 mg bid	1,200 mg/d	
Cardiovascular	Lidocaine	Burning neuropathic pain	50–100 mg IV	300 mg/h	2–50 mg/min q 5 min Adjust for renal or hepatic impairment
	Mexiletine		150 mg tid	1,200 mg/d	
	Tocainide		400 mg tid	2,000 mg/d	
Neuroleptics	Fluphenazine	Refractory pain	2.5 mg tid	40 mg/d	Used with pain complicated by nausea or delirium
Corticosteroids	Dexamethasone	Refractory bone and nerve pain	16 mg/d	96 mg/d	Used for malignant lesions, multiple side effects
	Prednisone		10 mg/d	60 mg/d	
Biphosphates	Pamidronate	Metastatic bone pain	90 mg IV	90 mg q 4 wk	Inhibit bone resorption
	Alendronate		10 mg q d	70 mg q wk	
Radiopharmaceuticals	Strontium-89	Bone pain	10 $\mu$ Ci		Possible thrombocytopenia
Neurostimulants	Dextroamphetamine	Somatic and visceral pain	5 mg bid	40 mg/d	Reduce sedative effects of opioids
	Methylphenidate		10–20 mg tid	60 mg/d	
	Pemoline		37.5 mg qam	112 mg/d	
	Caffeine		65 mg/d	200 mg/d	
Topical agents	Lidocaine	Peripheral neuropathy	q 12 h		Transdermal patch Causes burning sensation
	Capsaicin		3–4 times/d		
$\alpha_2$ -adrenergic agonist	Clonidine	Neuropathic pain	25–50 mg	150 mg/d	Epidural injection (significant hypotension may occur)
NDMA antagonists	Ketamine	Neuropathic pain	12.5–25 mg IV	150 mg IV test	Possible hallucinations and nightmares
			50 mg PO	250 mg/d	
Miscellaneous	Calcitonin	Bone pain	200 IU qd	200 IU/d	Intranasal
	Baclofen	Muscle spasm	5 mg tid	80 mg/d	GABA agonist
	Diazepam		5 mg tid	40 mg/d	Benzodiazepine
	Tizanidine		8 mg tid	36 mg/d	$\alpha_2$ -adrenergic agonist

bid, twice a day; IU, international unit; PO, by mouth; q 12 h, every 12 h; q 4 wk, every 4 wk; qam, every morning; qd, every day; qhs, at bedtime; qid, four times a day; tid, three times a day.

The authors will not assume liability for this table. No medication should be given until the complete prescribing recommendations, drug use indications, and potential side effects that are listed in the package insert with the product or contained in a drug reference manual are reviewed and understood thoroughly by the physician and patient. Drug dosages may need to be modified for the elderly.

<sup>a</sup> Dosage should be adjusted in elderly patients, patients on multiple medications, and patients with renal insufficiency or hepatic failure. Doses may be increased at varied intervals if pain relief is inadequate and dosage is tolerated. Doses and intervals titrated to effect.

**TABLE 49.8** Definitions Related to the Use of Opioids

**Addiction** (psychological dependence)—Addiction is a primary chronic neurobiological disease with genetic psychosocial and environmental factors influencing its development and manifestations. It is characterized by behaviors that include one or more of the following: impaired control over drug use, compulsive use, continued use despite adverse craving.

**Physical dependence**—Physical dependence is an adaptation that is manifested by a drug class–specific withdrawal syndrome that can be produced by abrupt sensation, rapid dose reduction, decreasing blood level of the drug, and/or administration of an antagonist.

**Tolerance**—Tolerance is a state of adaptation in which exposure to a drug induces change that results in a diminution of one or more of the drug's effects over time.

**Diversion**—Diversion is the illegal use or inappropriate use of medications. Diversion of controlled substances should be the concern of every health professional, but efforts to stop diversion should not interfere with prescribing opioids for pain management. Attention to patterns of prescription requests and prescribing of opioids is part of an ongoing relationship between a patient and health care provider and can decrease the risk of diversion.

Source: From Savage S, Covington EC, Heit HA, et al. Definitions related to the use of opioids for the treatment of pain: consensus documents from *The American Academy of Pain Medicine*, *The American Pain Society*, and *The American Society of Addiction Medicine*, 2001. <http://www.ampainsoc.org>; <http://www.painmed.org>; <http://www.asam.org>, with permission.

Many of the medications used in pharmacological intervention in pain may produce dependence, and some may lead to addiction in susceptible individuals. These medications include angiotensin, cannabinoids, muscle relaxants, opioids, sedatives, stimulants, and steroids. The clinical implications in management of physical dependence, tolerance, addiction, and diversion of medications are discrete and different phenomena (Table 49-8). Behavior suggestive of addiction may include inability to take medication according to agreed-upon schedule, taking multiple doses together, frequent reports of lost or stolen prescriptions, doctor shopping, isolation from family and friends, and use of nonprescription psychoactive drugs in addition to prescribed medications. Other behaviors that may raise concerns are the use of analgesic medications for other than analgesic affects (such as sedation), an increase in energy, a decrease in anxiety, intoxication, noncompliance with recommended nonopioid treatments or evaluations, insistent on rapid-onset formulation or routes of administration, and all reports of no relief whatsoever from any nonopioid treatments (276).

### Anesthetic Procedures

Blocking the nerve with a local anesthetic agent is one of the most common procedures in the management of chronic pain. Nerve block by itself, however, is not effective in relieving pain completely for a long period in the majority of patients.

Therefore, nerve blocks should be considered as only one of the therapeutic modalities used in the multidisciplinary pain clinic. Other factors, such as psychological problems and associated muscle tightness and weakness, should be treated by using other appropriate modalities. Nerve blocks are helpful in many patients by interrupting the pain process. It is the experience of many clinicians that when pain is temporarily interrupted by a local anesthetic block, often the patient's pain is permanently relieved. Nerve blocks are also useful in delineating the pain mechanisms and in blocking the pain when the patients are required to take part in physical therapy to mobilize the muscles and joints. Patients who have a nerve block followed by appropriate physical therapy usually have excellent results (277). The best results have been shown in patients requiring manipulation and mobilization of the knee and other joints. Continuous nerve block catheters can be placed perioperatively or in the outpatient setting to assist with pain control and physical therapy. There are various nerve block techniques used in pain clinics; the most common and useful include epidural use of a local anesthetic or opioid and peripheral nerve block (140,277). For more information on injection techniques, the reader is referred to Chapters 67 and 68.

Administration of a local anesthetic or opioid can provide prolonged relief by placement of a catheter in the epidural space, which can be left in place for several days to a few weeks. A local anesthetic or opioid can be administered intermittently or by continuous infusion, providing somatic and sympathetic block and analgesia for physical therapy. This is the most commonly applied technique in patients who have low back and lower extremity pain while they undergo physical therapy and mobilization (277).

Peripheral nerve block, such as suprascapular nerve block, is very useful in patients who have shoulder discomfort, frozen shoulder, or shoulder pain of other etiology. Patients can tolerate stretching and physical therapy after a suprascapular block with local anesthetic. In the upper extremities, brachial plexus blocks, especially continuous blocks performed by axillary or supraclavicular route, are of great value in patients requiring physical therapy. Other peripheral blocks, such as the lateral femoral cutaneous nerve block for patients with meralgia paresthetica, the femoral nerve block for patients with thigh and knee pain, and sciatic nerve and intercostal blocks, have been extremely useful in managing patients with chronic pain.

“Depo” types of steroids, injected into the epidural space, have been extremely useful in relieving nerve root irritation and inflammation in patients who have a herniated disk. They also have been effective in patients who have nerve root irritation secondary to radiation or a malignancy. Steroid preparations commonly used are methylprednisolone (40 to 80 mg), betamethasone (3 to 6 mg), dexamethasone (4 to 8 mg), and triamcinolone (25 to 50 mg). Although steroid preparations may be used to produce anti-inflammatory action, many of the steroid preparations contain various preservatives, such as benzyl alcohol, which may produce serious side effects, including paralysis. Agents with preservatives that are designated for

articular injections should not be used as epidural agents. Only preservative-free steroid preparations have been extensively used in the epidural space without producing significant neurologic damage (278). However, any particulate-based steroid can cause embolic spinal cord infarction if injected into the spinal arterial supply.

The steroids are injected into the epidural space close to the involved root. These injections can be performed at any level, including cervical, thoracic, or lumbar. The steroid preparations stay in the epidural space for 2 to 3 weeks. Repeat injections, if necessary, are given a minimum of 2 to 4 weeks apart. Many clinicians give a series of three injections regardless of successful response after the first injection. The preferred procedure is to administer one injection and wait 2 weeks in order to assess the patient's response. If the patient is significantly pain free, no further injections are administered. If there is minimal or limited response, then further injections are administered. If the patient does not respond to two or three epidural steroid injections, or the patient receives only short-term pain relief, then steroid injections are discontinued. Frequent injections of epidural steroid can produce problems related to chronic steroid administration as well as a remote possibility of infection.

Many clinicians combine the steroid injections with the administration of a local anesthetic agent. When this is done, the patient needs to be observed because the sympathetic block may produce postural hypotension, and the patient may become unable to ambulate due to motor block. No single technique has been proven to be more successful than another. Many clinicians use the caudal approach, using large volumes of local anesthetic agent or saline mixed with the steroid. This gives a 60% success rate as opposed to an 80% or higher success rate with a lumbar epidural technique, because caudally administered agents may not reach the site of pathology at L4 to L5 or L5 to S1 levels in significant concentration, owing to the leakage through the sacral foramina. Epidural steroid injection is also a useful technique in patients who have neural irritation. In addition, steroids may be injected into the subarachnoid space, especially in patients who have had multiple surgeries and in whom the epidural space has been obliterated. These patients, especially those with arachnoiditis, show significant pain relief. Epidural steroids can produce an initial increase in pain for 8 to 24 hours.

### Clinical Research in Chronic Pain Treatment

Multiple reports have been published providing guidelines for clinical research in pain (3,121,200,279,280). There is continued need for more rigorous scientific research on most aspects of chronic pain, including natural history, etiology, diagnosis, therapy, and the cost effectiveness of treatment. Determining the efficacy of pain treatment from the medical literature is difficult because studies fail to meet basic scientific standards for internal validity and applicability of the results. Much research has been based on a collection of anecdotal or highly selected cases from which the true outcome of treatment is impossible to extrapolate.

Some critics continue to suggest that researchers often neglect factors in chronic pain treatment. These factors include the high selection factors of patients in pain clinics, medical exclusion criteria, financial exclusion criteria, patient refusal to accept treatment, and patient attrition (281). Outcome studies that include the brief duration of follow-up periods, vague criteria used for establishing the success of the therapeutic intervention, and other factors cast doubt on the applicability of the results to the general population. In examining the significance of intervention in outcome studies, it is important to consider the limiting factors imposed by the methodology.

The diversity of techniques in pain research has resulted in limited consensus regarding the appropriate diagnosis and treatment of many chronic pain syndromes. Unorthodox therapies continue to proliferate, with few standard treatments shown to be more effective than no medical intervention or placebo. For progress to be made in the management of chronic pain, reasonable research design must be incorporated into the evaluation of treatment efficacy. Contemporary studies should assess outcomes measured within recognized domains of clinical significance, including pain, physical functioning, emotional functioning, participant ratings of improvement and satisfaction with treatment, symptoms and adverse events, and participant disposition (282,283).

## COMMON PAIN SYNDROMES: DIAGNOSIS AND TREATMENT

### Myofascial Pain

Myofascial pain syndromes are commonly seen when evaluating and treating patients for chronic pain. Trigger points are characterized by pain originating from small circumscribed areas of local hyperirritability and myofascial structures, resulting in local and referred pain (178). The pain is aggravated by stretching the affected area, cooling, and compression, often giving rise to a characteristic pattern of referred pain (179,180). Although the exact pathophysiology of the trigger point phenomenon has not been identified, myofascial pain syndromes appear to be initiated by trauma, tension, inflammation, and other unidentified factors. The trigger point acts as a source of chronic nociception. The resultant muscle dysfunction and altered mechanics lead to the referred pain and associated phenomenon.

Trigger points may occur in any muscle or muscle group of the body. They are commonly found in muscle groups that are routinely overstressed or those that do not undergo full contraction and relaxation cycles. In the upper body, the groups of muscles involved commonly include the trapezius, levator scapulae, and infraspinatus. In the lower body, they include the gluteal, tensor fasciae latae, quadratus lumborum, and gastrocnemius muscles.

Trigger points are best located by deep palpation of the affected muscle so as to reproduce the patient's pain symptom both locally and in a referred zone. When they are present,

passive or active, stretching of the affected muscle routinely increases the pain. The muscle in the immediate vicinity of the trigger point is often described as ropy, tense, or having a palpable band. Compared with equivalent pressure in palpation to normal muscle, the trigger point region displays isolated bands, increased tenderness, and referred pain.

The most reliable method of treating trigger points consists of routine, regular stretching to restore the normal resting length of the muscle. Methods to interrupt the pain cycle include injection or needle stimulation of the hypersensitive trigger points (282–287), coolant sprays (178), relaxation therapy, and pressure techniques (285). Botulinum toxin injection has been utilized to provide pain relief for weeks to months by selectively weakening the painful muscles (288). After interrupting the pain cycle, the treatment is directed at restoring the normal resting muscle length with a regular routine stretching program of the involved muscle groups. This may be accomplished with physical modalities including heat and electrical stimulation, or cold, along with the correction of poor body mechanics (289). Psychological intervention may be necessary if long-standing stress and tension are the underlying cause of the problem. A long-term home modality and stretching program is essential in the management of patients with myofascial pain. Attention to body mechanics, stress, and daily routines may significantly alter their functional capabilities. For more information on myofascial pain, the reader is referred to Chapter 35.

### Cumulative Trauma Disorders

Repetitive overuse is a type of disorder identified as a causative factor of many industrial injuries. This is a common problem seen in the rehabilitative industrial practice referred to as *repetitive motion disorders*, *occupational overuse injuries*, or *repetitive strain injuries*. Cumulative trauma disorders now account for greater than 50% of all workers' compensation claims (290). Upper-limb cumulative trauma disorders are far more common than lower-limb trauma disorders.

Etiology of cumulative trauma disorders appears to be repetitive motion and stress, resulting in microtrauma primarily to the muscle and tendon. Less often, this microtrauma involves the ligaments, joints, cartilage, bones, and musculoskeletal structures. Presenting symptoms may include tendonitis, muscle strain, ligamentous injury, bursitis, myofascial pain, compression neuropathies, and intravertebral disc disease.

Treatment of cumulative trauma disorders often requires aggressive intervention and adaptation of the workplace (290). If a patient's problem fails to resolve, careful screening as to the aspects of repetitive motion needs to be assessed, and careful discussion with the patient's supervisor/employer needs to occur in order to determine an adaptive environment to bring about satisfactory problem resolution. An altered work environment should be designed for the worker to perform different or rotating work tasks, using different muscle groups that in turn will minimize cumulative trauma disorders. For more information on cumulative trauma disorders, the reader is referred to Chapter 36.

### Pain from Peripheral Neuropathy

Pain is a common feature of peripheral neuropathy that is due to diabetes, amyloidosis, alcoholism, polyarteritis, Guillain-Barré syndrome, brachial neuritis, acquired immune deficiency syndrome (AIDS), porphyria, and riboflavin deficiency. This pain may be of either a constant or an intermittent nature and is often described as burning, aching, or lancinating. It may occur with or without signs of sensory loss, muscle weakness, atrophy, or reflex loss (291,292).

Evidence-based recommendations for the pharmacological management of pain from peripheral neuropathy include anticonvulsants (pregabalin, gabapentin), tricyclic antidepressants (TCAs such as amitriptyline, desipramine), dual-action selective serotonin and norepinephrine reuptake inhibitors (SSNRIs such as venlafaxine, duloxetine), and topical lidocaine as first-line medications in alleviating the pain from peripheral neuropathy (253,254,259–261,293–296). These medications may be used in combination, as each may have a different mechanism of action. It is often suggested that rehabilitative interventions include exercise, desensitization training, TENS, and medications. NSAIDs are often used in association with the above adjunctive agents and simple physical measures (202,297).

Pain resulting from alcoholic neuropathy typically resolves after the correction of nutritional deficiencies. Pain resulting from polyarteritis may resolve after corticosteroid treatment, whereas pain secondary to cryoglobulinemia may resolve with plasmapheresis. Pain from brachial neuritis and other self-limiting conditions resolves spontaneously in weeks to months. Pain secondary to diabetic neuropathies rarely resolves completely. Drugs that induce painful peripheral neuropathies include isoniazid and hydralazine, which cause a decrease in tissue levels of pyridoxal phosphate, as well as nitrofurantoin, which has neurotoxic effects.

The patient with chronic pain due to peripheral neuropathy has many of the associated problems of chronic pain, including depression, inactivity, disuse syndrome, and significant alteration of lifestyle. Psychological intervention and physical therapy are important aspects of treatment in these patients. Medication, conventional physical therapy modalities, TENS, and general conditioning programs are often helpful, as are psychological programs and other nonpharmacologic methods of pain control.

### Complex Regional Pain Syndrome

A contributing factor in many chronic pain syndromes is CRPS resulting from overactivity of the sympathetic nervous system. This is often reported as continuous burning pain in an extremity after trauma. CRPS I or *reflex sympathetic dystrophy* refers to cases of minor injury or no injury, with resulting overactivity of the sympathetic nervous system. CRPS II or *causalgia* refers to partial injury to a major nerve, followed by the symptoms of sympathetic system overactivity. Examples include shoulder-hand syndrome, post-traumatic edema, Sudeck's atrophy, and various other syndromes in which sympathetic overactivity seems to be the primary etiologic factor.

Dysfunction of the sympathetic nervous system is by no means the sole component of CRPS (298,299).

The etiology of the sympathalgia is not distinct. The most common aspect of a sympathalgia is burning pain. Associated with the hyperpathia are hypersensitivity to touch and relief of pain with an appropriate sympathetic nerve block. The patient also may show evidence of overactivity of the sympathetic nervous system, including hyperhidrosis and vasoconstriction, resulting in the cooling of the extremity. When accompanied by disuse, this may produce trophic changes, including shiny thin skin, loss of hair, and demineralization of bone (300).

Diagnosis of CRPS is difficult. The patient's pain is usually diffuse and does not correspond to dermatomal or peripheral nerve patterns. Thus, these patients are often diagnosed as having psychogenic pain. Anatomic or pharmacologic nerve blocks may establish the diagnosis. Psychogalvanic reflex tests and thermography may be useful in documenting sympathetic nervous system hyperactivity.

Pharmacological treatments have included NSAIDs (tramadol), sodium channel blockers (intravenous [IV] lidocaine), *N*-methyl-D-aspartate [NMDA] receptor blockers (ketamine, dextromethorphan, memantine), calcium-regulating drugs (calcitonin, clodronate, alendronate), free-radical scavengers (transdermal dimethylsulfoxide [DMSO], oral *N*-acetylcysteine [NAC]),  $\alpha_2$ -adrenoceptor agonist (clonidine), and oral phenoxymethamine (301,302).

The most effective invasive treatment of CRPS consists of an appropriate sympathetic nerve block using a local anesthetic agent (278,303). If the problem originates in the head, neck, upper limb, or upper thorax, a stellate ganglion or a cervical sympathetic block at the C6 level may be useful (304). If the pain is in the upper abdominal area, sympathetic blockade can be achieved using the celiac plexus block. Pain originating in the lower limb requires a lumbar paravertebral sympathetic block at the L2 level (277). Patients with a history of long-standing pain may receive only temporary pain relief from the local anesthetic blocks. IV regional bretylium has been reported to provide a statistically significant decrease in CRPS symptoms (305); however, neither IV regional guanethidine nor reserpine provided any better relief of CRPS symptoms than placebo in randomized, double-blind studies (306,307). If the patient does not receive lasting pain relief from sympathetic blocks or the IV regional technique, then permanent interruption of the sympathetic pathways may be accomplished by a neurolytic injection of the sympathetic trunk or surgical sympathectomy. Unfortunately, neurolytic techniques are not recommended for the long-term control of neuropathic pain that is due to nerve regrowth, central spinal reconfiguration, and neuroma formation. Pain normally returns in 6 to 12 months following neurolytic intervention (303). Alternatively, patients with neuropathic pain may also benefit from spinal cord stimulation. The system can be implanted if trial stimulation is successful (308–310).

The patient may also have nonsympathetically mediated neuropathic pain and musculoskeletal pain stemming from the initial injury and subsequent disuse. Often, the patient receives

relief of pain at rest with the sympathetic block, but when the limb is moved during physical therapy, the patient experiences significant pain. This pain is secondary to tight muscles or stiffness of the joint, where the noxious input is carried through somatic fibers. Peripheral nerve, plexus, or epidural block can treat this type of pain, and can be achieved with single injections or continuously with percutaneous catheters. In conjunction with sympathetic blocks or these other procedures, intensive physical therapy should be instituted (311) to maximize the benefits.

When treating a patient with long-standing pain that is due to CRPS, it is important to consider the psychological aspects. Patients who develop RSD may have enhanced sympathetic pain, secondary to psychological tension. Post-traumatic stress disorder is also a common but unidentified psychological problem in CRPS patients. Appropriate psychological and psychiatric consultation for relaxation training and biofeedback, in addition to other treatment modalities, is important. Psychological factors must be adequately treated; otherwise, the patient is unlikely to improve regardless of other interventions (312).

### Phantom Limb Pain

Phantom limb pain involves an amputated portion of the body. The etiology of phantom pain appears to be related to peripheral, spinal, and central factors. Peripheral components of phantom limb pain appear to be the result of sensation due to loss of previously present peripheral nerve activity triggering changes in the central nervous system. Development of abnormal activity in a neuroma or dorsal root ganglion results in pain fiber transmission and an alteration in ion channel activity at site of injury resulting in pain fiber activation. Spinal-level factors involved in phantom limb pain include deafferentation of neurons and their spontaneous and evoked hyperexcitability resulting from the loss of large A-afferent nerve fiber input in the dorsal horn cells with an unopposed C-fiber input. Cortical reorganization has been observed in the primary motor and somatosensory cortex in humans after amputation. These reorganizational changes appear to be a significant factor in the occurrence and intensity of phantom limb pain. The remapping of regions of the brain receiving touch, pain, and temperature input from the amputated limb to other parts of the brain appears to be an etiology of phantom limb pain. Pain may be continuous, in character with intermittent exacerbations. It is often reported by patients as cramping, aching, or burning, with occasional superimposed electric-like components. Reported incidence of phantom limb pain is highly variable often due to the setting and circumstances in which the data were collected. Prospective research suggests approximately 82% of patients experience phantom pain following amputation. It is estimated that 65% experience phantom pain at 6 months, and 59% experience phantom pain 2 years after amputation. Severe disabling phantom limb pain incidence is reported at 10% after several years. Of note are reports that severe pain occurs more often with proximal amputations.

The current data do not suggest a predisposition for phantom pain among traumatic amputees, elderly amputees, those with pain in the amputated limb before amputation, or poor preamputation interpersonal relationships (313). Phantom limb pain does not appear to be correlated with amount of time after amputation or use of prosthesis. The incidence of phantom limb pain is independent of age, gender, level of amputation, employer, or age after 8-years old (313–318). Most studies have found no significant relationships between preoperative limb pain and persistent phantom pain (319,320). Multiple modalities, adjuvant medications, and anesthetic and surgical procedures have been used in the treatment of phantom limb pain with varying long-term success. Although more than 70 methods of treating phantom limb pain have been identified, successful treatment of persistent types of pain is not commonly reported (292,294,321–327). Transcutaneous nerve stimulation, tricyclic antidepressants, anticonvulsants, calcitonin, lidocaine, mexiletine, and mirror therapy have been used with varying success. Chemical sympathectomy or neurosurgical procedures also have had variable success. Treatments yielding a temporary decrease in pain include analgesics, anesthetic procedures, stump desensitization, physical modalities, and sedative/hypnotic medication. One survey reported that treatments reducing residual limb pain problems also resulted in decreased phantom pain (317). Studies of various therapeutic regimens have reported up to a 70% efficacy in the treatment of phantom limb pain, but reviews of most with long-term follow up suggest a limited response to any intervention. Animal studies report that functional reorganization of the primary somatosensory cortex correlates with the intensity of phantom limb pain after amputation of a limb (328). Underlying mechanisms for phantom limb pain include reorganization that appears to occur at the dorsal horn of the spinal cord, in the thalamus, and in the cortex.

*Residual limb pain* is pain at the site of the limb amputation. Residual limb pain is common, with approximately 57% of patients experiencing residual limb pain following amputation. It is estimated that 22% experience residual pain at 6 months, and 10% experience residual pain 2 years after amputation. Severe disabling residual limb pain incidence is reported at 5% after several years (313–316). Residual limb pain may be rated as more severe than the patient's phantom limb pain. Residual limb pain was rated as the worst problem by 33% of the patients, phantom limb pain by 24%, back pain by 17%, and sites other than the involved limb by 26%. In the early evaluation of phantom limb pain, it is important that stump pain that is due to a neuroma is ruled out as the etiology of the pain reports. The pain caused by a neuroma is sharp, often jabbing, pain in the stump and is usually aggravated by pressure or by infection in the residual limb. Pain is often elicited by tapping over a neuroma in a transected nerve. The increased sensitivity of sprouts from cut peripheral nerves to noradrenalin and adrenaline may partially explain why adrenergic-influenced emotional states (i.e., stress or anxiety) occasionally provoke attacks of phantom limb pain.

## Neuroma and Scar Pain

Injury to the nerve with a resulting neuroma or entrapment of the branches of the nerve in scar tissue can produce disabling pain. Neuromas are suspected when numbness appears in the distribution of a particular nerve and when pain is produced by palpation of the neuroma. It has been shown that the nerve fibers in the neuroma develop  $\alpha$  receptors, which respond to catecholamines with spontaneous firing and pain production. Painful neuromas are difficult to treat; many patients continue to have pain despite multiple attempts at surgical excision of the neuroma. Suspected scar pain can be evaluated by picking up the scar from the deeper tissues with two fingers and palpating. If this does not reproduce the patient's pain, the pain is probably not originating in the scar tissue. Pain that is due to neuroma or scar tissue can be associated with CRPS. Diagnosis can be established by infiltration of the scar or the neuroma with a local anesthetic agent, resulting in complete pain relief (141).

Repeated injection of a local anesthetic agent has proven to be an extremely useful technique. This should be followed by appropriate physical therapy to the scar, usually ultrasound followed by stretching or deep massage of the scar. This type of treatment has provided permanent or prolonged pain relief for longer than 6 months in many patients. When the local anesthetics, with or without steroids, do not provide prolonged relief, other methods should be considered. Cryoanalgesia using a cryoprobe and freezing the neuroma for 1 minute at 20°C has been used with good success (329). The advantage of using a cryoprobe lies in the fact that it is a physical method of blocking the nerve without producing further neuroma or neuritis. Neurolytic agents such as phenol or alcohol have been used to relieve neuroma and scar pain. Incomplete block with these agents can result in neuritis, producing severe pain. These neurolytic techniques should be used only after repeated injections of local anesthetics produce consistent pain relief proportional to the duration of action of the local anesthetic agent. Although surgical revision of the scar is often considered, it is not very successful when the scar cannot be stretched out and there is significant nerve entrapment.

## Cancer Pain

Cancer pain is acute or recurrent pain secondary to a chronic condition. Unbearable pain is one of the greatest fears and a major source of morbidity for patients with cancer (294, 330–332). Clinical experience suggests that patients with cancer pain are treated most effectively with a multidisciplinary approach, including multiple modalities, appropriate analgesic drugs, neurosurgical and anesthetic procedures, psychological intervention, and supportive care (12–14). The goals of pain therapy for cancer patients are a significant relief of pain to maintain the functional status they choose, a reasonable quality of life, and a death relatively free of pain.

Noninvasive treatment measures are often used singularly for mild to moderate pain and in combination with drug therapy for moderate or severe pain. Commonly used noninvasive measures include cutaneous stimulation, thermal modalities,

and behavioral intervention. Their advantages include low risk of complications, low cost, and few serious side effects.

Nonopioid, opioid, and adjuvant analgesic drugs are the primary therapy for patients with cancer pain. Anesthetic, psychiatric, behavioral, and occasionally neurosurgical approaches are commonly used with pharmacologic intervention. This combination of treatment is estimated to provide adequate pain relief in at least 90% of the patients with cancer pain (333).

The World Health Organization has recommended a systematic approach for the selection of pharmacologic agents for treating patients with cancer pain (334,335). The protocol is based on the premise that doctors and health care professionals should know how to use a few simple drugs well. A three-step analgesic ladder is the scheme that is used for analgesic selection and is summarized as follows:

1. Those patients who have mild to moderate pain should be initially treated with a nonopioid analgesic (see Table 49-4), such as aspirin or one of the other NSAIDs, and adjuvant analgesic (see Table 49-7) if indicated.
2. Patients who have moderate to severe pain or are not able to achieve adequate relief with step 1 should be started on a weak oral opioid (see Table 49-5), such as codeine, along with a nonopioid and an adjuvant analgesic if indicated. Pain secondary to soft tissue and bone metastases usually has a limited response to opioids. In these situations, NSAIDs are indicated at all levels of treatment.
3. For patients who have very severe pain or do not achieve adequate relief on step 2, the regimen should include treatment with a potent opioid, such as morphine or methadone (see Table 49-6) with or without an NSAID, and with or without an adjuvant analgesic if indicated (336).

Opioid analgesics are the drugs of choice for relief of intractable pain due to cancer (12). Slow-release morphine and methadone are extremely useful analgesics in the treatment of cancer pain. The object is to titrate the level of analgesic to the optimal dose that prevents the recurrence of pain. Oral medications should be used whenever possible because they facilitate ambulatory care, encourage greater independence, and do not represent heroic intervention to the patient. It is important to remember that the maximum recommended dosages of opioid medications were derived mainly from postoperative parenteral single-dose studies and are not applicable to administration by mouth in the long-term treatment of pain in advanced cancer. Dependency and respiratory depression should not be feared because they are seldom a problem. The most serious side effects of drug therapy, which should be prevented or treated, include constipation and nausea.

Supportive care is designed to maintain the cancer patient in an outpatient setting, with pain a common cause for readmission to the hospital. Nerve blocks and neurolytic procedures are most often used to provide pain relief in the thoracic and abdominal regions (140–141,278). These procedures are often performed in the outpatient setting and often provide

pain relief for up to 6 months. Supportive care may involve a hospice, hospital-based care teams, visiting nurses, and social services. The primary goal of the physician is to maintain the quality of life for the cancer patient to the end, allowing the patient a death with dignity.

It is essential that during a cancer patient's hospitalization, outpatient treatment, and everyday activities, they maintain their functional skills, strength, and mobility. Progressive immobilization is an insidious aspect of this disease and is often iatrogenic. Although radiation and chemotherapy may transiently render a patient unable to perform activities, the patient needs to be consistently evaluated and involved in active physical, occupational, corrective, and recreational therapy programs. The physiatrist may offer multiple methods of combating immobility and its morbidity. For additional information on cancer rehabilitation, the reader is referred to Chapter 44.

There are multiple invasive measures to control cancer pain. The most common is the surgical removal of all or part of the tumor with the hope of relieving pain and obtaining a cure. Radiotherapy or chemotherapy also may relieve pain by shrinking the tumor. Common invasive anesthetic procedures include trigger point injections and nerve blocks. Myofascial pain syndromes are often the result of inactivity and disuse and are commonly found in the cancer patient. Neuropathic pain may result from direct tumor invasion or as a side effect of chemotherapy. Patients who have side effects with large doses of opioids may derive long-term benefit with a chronically implanted epidural catheter or an intrathecal catheter and pump to administer opioids and/or clonidine (337,338). Multiple neurosurgical procedures have been used for the control of cancer pain (339).

### Herpetic Neuralgia

*Herpes zoster* (shingles) is a reactivation of the varicella (chicken pox) virus, which has remained latent. The viral inflammation of the dorsal nerve root and ganglion causes vesicle formation and severe burning, aching, and lancinating pain in a radicular distribution. During the acute stage, a course of antiviral medication, along with NSAIDs and sympathetic blocks, provides excellent pain relief (340). The majority of patients recover from the acute episode in approximately 2 weeks without sequelae. However, some patients develop postherpetic neuralgia secondary to deafferentation from neuronal cell death with and without allodynia. Postherpetic neuralgia is uncommon in patients younger than 40 years of age but occurs in more than 50% of patients older than 60 years of age after an episode of herpes zoster (341). Skin biopsies of patients after herpes zoster show a decrease in density of cutaneous nerve endings in the patients with postherpetic neuralgia when compared with patients without postherpetic neuralgia (342–343). It has been suggested that an innervation level of approximately 650 neurites per mm<sup>2</sup> may be necessary to avoid postherpetic neuralgia (344).

Multiple reports indicate that postherpetic neuralgia may be prevented if the patient is treated with a sympathetic

block within 1 month after the onset of herpes zoster (140). Postherpetic neuralgia is, thus, a preventable syndrome, but it is a difficult problem once established. A significant number of patients experience pain relief with sympathetic blocks. If the syndrome is allowed to progress untreated for 3 months to a year, it becomes more difficult to treat (269).

The most effective treatment for the management of established postherpetic neuralgia is the use of a tricyclic antidepressant, such as amitriptyline, in small doses (269,293). Most patients obtain pain relief with 25 to 75 mg administered at bedtime. If the patient does not get complete pain relief with administration of tricyclic antidepressants alone, fluphenazine may be added, beginning with 1 mg at bedtime and progressing as needed to a maximum dosage of 1 mg three times a day. Anticonvulsants (such as gabapentin, phenytoin, and carbamazepine) have been administered with variable results (259, 277). Pain reduction has been reported with topical lidocaine (345–347) for herpetic neuralgia. Opioids and tramadol are considered second-line treatment options in most circumstances. Topical capsaicin and valproate are suggested as third-line interventions. Peripheral nerve blocks and destructive neurosurgical procedures have not proved useful in treating established postherpetic neuralgia.

### Pain in Spinal Cord Injury

Pain related to spinal cord injury is often complex and multifactorial. Spinal cord injury pain may be broadly classified into nociceptive pain (musculoskeletal and visceral) and neuropathic pain located above level, at level, and below level of the spinal injury (Table 49-9). The reported prevalence of chronic pain in the population with spinal cord injury is variable with an average of 65%, approximately one-third rate the pain as severe (348).

Many of the nociceptive types of pain are variations of those found in patients without spinal cord injury and are treated in a similar fashion with adaptation to the underlying injury. However, patients with spinal cord injury are more susceptible to mechanical instability of the spine that is due to trauma of the musculoskeletal system, muscle spasm pain that is due to trauma to the neurologic system, as well as both overuse and nerve-compression syndromes primarily involving the upper extremities.

Mechanical instability of the spine is usually best treated with NSAIDs and opiates (as needed), as well as immobilization using orthosis or surgical fusion. These are effective treatments in most patients. Pain that is due to muscle spasm is best treated with antispasmodics, motor point blocks, or botulinum toxin to decrease spasticity. Secondary overuse syndromes are often relieved by rest and NSAIDs, with significant adaptation by the patient and modification of environmental factors. Nerve-compression syndromes are often relieved through the use of orthotics or surgical decompression. Visceral nociceptive pain is often due to afferent input from the sympathetic nervous system and may be due to underlying pathology. A headache that is due to autonomic dysreflexia is a medical emergency and should be treated appropriately.

**TABLE 49.9** Classification of Pain Related to Spinal Cord Injury

Nociceptive
Musculoskeletal (often dull, aching, movement, decreased with immobilization, responsive to NSAIDs and opioids)
Secondary overuse syndromes
Bone, joint, muscle trauma, or inflammation
Mechanical instability
Bone joint, muscle trauma, or inflammation
Scar infection
Muscle spasm
Visceral structures (often dull, cramping, burning, constant but fluctuating pain in the abdomen with preserved innervation)
Regional calculus
Bowel or sphincter dysfunction
Dysreflexic headache
Neuropathic [often sharp, shooting, burning, electrical sensation (hyperalgesia, hyperesthesia)]
Above level (located in region of sensory preservation)
Compressive mononeuropathies
Complex regional pain syndromes
Routinely treated as neuropathic pain of peripheral nerve origin
At level (located in segmental pattern of level of injury)
Nerve root compression (including cauda-equina)
Syringomyelia, spinal cord trauma/ischemia (transitional zone, etc.)
Presents with an ascending neurological deficit often with alterations in pain/temperature
Dual level cord and root trauma and double lesion syndrome
Below level (located diffusely below level of injury)
Spinal cord trauma/ischemia (central dysesthesia syndrome, etc.)
Phantom sensations

With neuropathic pain, evidence suggests that trauma and neural alterations of the pain pathways are primarily involved (349–353). Patients describe their pain as having one or more of the following components at the level of injury: lancinating, burning, or stabbing pain in a radicular distribution. This pain may also be related to spinal instability or nerve-root entrapment. Pain is typically relieved by opioids, neuropathic pain medications, and spinal decompression, if necessary. This includes cauda-equina injury, which is neuropathic pain of peripheral nerve origin that has a burning sensation routinely affecting the groin and bilateral lower extremities. Segmental deafferentation pain often occurs at the border of sensory loss. Transitional zone pain is often associated with allodynia and hyperalgesia and may respond to neuropathic pain medications, epidural or somatic root blocks, dorsal root entry zone (DREZ) procedures, or spinal cord stimulation. The combination of spinal cord and root trauma often results in severe burning pain over a region that is otherwise denervated. Pain with root evulsion may be responsive to neuropathic pain medications, DREZ procedures, or spinal cord stimulation. The segmental deafferentation pain may be secondary to spinal cord trauma or ischemia. Neuropathic pain below the

level of entry is often referred to as *deafferentation* or *central dysesthesia syndrome*, commonly described as burning, tingling, numb, aching, or throbbing. Pain is usually constant and unrelenting. Pain may be relieved by neuropathic pain-relieving medication, intrathecal opioids, and clonidine, and occasionally by dorsal column stimulator. This is located diffusely below the level of injury (354–358). Studies indicate that 66% of all patients with spinal cord injury have pain that is mild to moderate in severity. Approximately 37% of patients with high thoracic and cervical lesions and 23% of patients with low thoracic and lumbosacral spinal cord injury lesions experience severe pain (355–361). Pain after spinal cord injury is common, poorly understood, complex, and often difficult to treat. Also note that 50% of patients with cauda-equina syndrome report severe pain. Pharmacologic and nonpharmacologic treatments for pain in patients with spinal cord injury have a minimal number of subjects per treatment approach, and only a limited number of studies have been subjected to randomized, controlled trials.

The precise etiology underlying pain in spinal cord injuries is not known, but evidence suggests that trauma-induced alterations of the pain pathways are primarily involved (350–353). Hypersensitivity of the structures in the ascending pathway may play a role. Patients describe their pain as having one or more of the following components: burning in body parts below the injury, a deep, aching sensation over and around the site of injury, and radicular with lancinating characteristics. Burning pain in spinal cord–injured patients may be a variation of deafferentation pain occurring as a result of loss of inhibitory or augmentation of excitatory influences. The most effective treatments of this type of pain include gabapentin and SSRIs and neuroaugmentative techniques (362).

Spinal fracture site pain results from an alteration of body mechanics causing pain-sensitive structures to be stretched or compressed. This mechanical pain may be the result of vertebral end-plate fractures, annulus fibrosus tears, or internal disc herniation after a spinal fracture (363). Fracture site pain or mechanical pain is often exacerbated by activity. NSAIDs, trigger point injections, TENS, cognitive/behavioral techniques, and adjuvant medication may be used. Orthotics also may be used to decrease the mechanical stress and alleviate the underlying etiology (364,365).

Radicular pain in these patients may be secondary to compression of nerve roots by a herniated nucleus pulposus, fracture fragment, dislocated vertebra, or the results of traumatic arachnoiditis (366). For additional information on spinal cord injury, the reader is referred to Chapter 27.

### Pain in Multiple Sclerosis

Multiple sclerosis is a chronic, remitting, and relapsing disease characterized by multiple foci of demyelination that are randomly distributed in the white matter of the central nervous system. Pain in multiple sclerosis has a prevalence of 50% to 85% (367–370). Of those individuals with pain from multiple sclerosis, the distribution is central neuropathic pain (41% to 48%), trigeminal neuralgia (9%), peripheral neuropathic pain

(4%), spasticity pain (1%), pain of unknown origin (1%), and nociceptive pain (36%) occurring singularly or in combination (368). Patients often present initially with paroxysmal lancinating and intense burning pain that primarily affects the face, shoulder region, or pelvic girdle. In multiple sclerosis, the central pain usually involves the bilateral lower extremities (368). Treatment of pain resulting from multiple sclerosis has been limited. Minimal response has been shown to tricyclic antidepressants, carbamazepine, and phenytoin. Limited response has resulted with gabapentin (371). If the patients have intrathecal baclofen pumps, neuropathic pain adjuvant medications can be added to the infusion. For additional information on multiple sclerosis, the reader is referred to Chapter 25.

### Poststroke Pain

Pain after a cerebral vascular accident may be secondary to multiple etiologies, including central pain, CRPS, pain that is due to spasticity, and pain from dysfunction of the affected extremities. Central pain is due to a lesion or dysfunction of the central nervous system that is often characterized as an agonizing, burning pain on the side contralateral to that of the lesion. Approximately 90% of all cases of central pain are caused by cerebral vascular accidents, and 78% of these are supratentorial. Central nervous system lesions producing central pain can be extremely small, especially if located in central pathways; approximately 8% of stroke patients report central pain during the first year. Almost 100% of central pain patients are affected by change in temperature perception. Pain is constant in 85% of the patients and intermittent but daily in 15%. Pain is primarily burning, aching, prickling, and lancinating. Patients make the point that central pain is not truly pain, but an unpleasant sensation that drastically affects their quality of life. Neuronal reorganization of the central nervous system architecture is most likely the cause of central pain. The plasticity of the central nervous system may result in changes in receptor structure and function that are likely to be delayed in onset. Central nervous system neurons are responsible for nociceptive perception and can exhibit long-lasting changes and responsiveness after transient or permanent damage in input. Either excitatory or inhibitory mechanisms can be affected, and as this responsiveness changes, so does modulation of the signals. Central pain that is due to thalamic infarction is often characterized as an agonizing, burning pain on the side contralateral to that of the lesion. Pain to minimal cutaneous stimulation as well as aggravation by emotional stress and fatigue are characteristic findings. Sensory alteration is variable in these patients, with minimal findings of motor weakness. Central pain that is due to lesions involving central thalamic spinal tracts may be manifest in pain distributed to the level of the tract involved. This results in loss of pain and temperature perception on the contralateral side at the level below the injury. Central pain of tract origin is similar to pain of thalamic origin but is usually less intense. This pain may be described as burning, pulling, or swelling. Information on central pain syndromes is scarce, with treatments limited in efficacy (372). Treatment options include sympathetic blockade (373), multiple medication

(374), and TENS (375). In treatment of central pain, no one pharmacological, surgical, or other therapeutic intervention has proven effective. After surgery, pain always recurs, usually within 3 to 6 months. Initial treatment includes antidepressants (amitriptyline, nortriptyline, trazodone), opioid analgesics, anticonvulsants (carbamazepine, phenytoin, gabapentin), transcutaneous electrical nerve stimulation, and psychosocial support. Although there are many targets for treatment, with at least five neurotransmitters implicated and mediated through first-, second-, and third-order neurons, no one pharmacological treatment has proven effective; hence, rarely is surgical intervention recommended. Central pain is also noted with Dejerine-Roussy syndrome. The second step of treatment includes adjuvant agents, including clonidine and  $\beta$ -blockers, as well as opioid agonist/antagonists, including talwin and mexiletine. Step three includes dorsal column stimulators, DREZ, ablation, thalamic stimulation, and deep brain stimulation.

Spasticity secondary to stroke may result in pain. This may be treated with medication or nerve blocks (376). Studies have suggested that patients with spasticity and pain in the hemiplegic upper limb may benefit from selective posterior rhizotomy in the DREZ (377). Poststroke pain that is due to dysfunction of the affected extremities is most often manifest in the upper extremity. This pain may be the result of shoulder subluxation,

decreased range of motion because of adhesive capsulitis, or brachial plexus injury (278).

Other factors of affected limb dysfunction include bicipital tendonitis, arthritis, fracture, heterotopic ossification, and knee/ankle instability. Appropriate use of modalities, as well as orthotics and assistive devices, is indicated in the resolution if some of these problems are contributing to the patient's pain (378). For additional information on stroke rehabilitation, the reader is referred to Chapter 23.

### Fibromyalgia

FM is a common type of nonarticular, chronic pain involving the musculoskeletal system, with a prevalence ranging from 2% to 12% in the general population and primarily involving middle-aged women (379,380). In 1990, the American College of Rheumatology (ACR) established diagnostic criteria for FM that currently remains the standard. FM is described as chronic, widespread nonarticular musculoskeletal pain that may not be attributed to specific structural or inflammatory etiology, with diagnostic markers involving both sides of the body, above and below the waist, and axial skeletal system. In addition, there should be at least 11 tender points among 18 specific sites (Fig. 49-18) (381). It is notable that there have been concerns that the defined criteria are too subjective, and

**FIGURE 49-18.** Anatomical locations of tender points in fibromyalgia. At least 11 of 18 tender points must exhibit painful sensitivity to 4 kg of digital palpation pressure (4 kg = pressure to blanch the examiner's thumb nail to its midpoint). The history of widespread pain for greater than 3 months and above sensitivity to 11 or more tender points has demonstrated moderately high sensitivity (88%) and specificity (81%) for patients with fibromyalgia.

that FM should be classified as a functional somatic syndrome and not a rheumatologic disorder (382).

In addition to pain, other complaints with FM are fatigue, cognitive dysfunction (memory loss, searching for words), psychological distress, sleep disturbance (insomnia and disordered sleep), stiffness, paresthesia, anxiety, and irritable bowel syndrome. FM does not cause joint pathology, but may occur in the presence of other rheumatologic disorders. There are no specific lab abnormalities associated with FM. The pathogenesis of FM is unknown, but evidence suggests that it may be secondary to abnormal processing of sensory stimuli in which sensory input is amplified at the brain and spinal cord, thus leading to an increased experience of pain (383). The sensory detection threshold is normal, with an increased sensitivity to most stimuli in patients with FM. The tender points are locations where the general population is more sensitive to palpation and demonstrate no specific pathology in the patient with FM. However, these points are more tender than normal in patients with FM due to lowered pain threshold (382,384). There is also an increased incidence of depressive and anxiety disorders associated with a common pathophysiological pathway in neurotransmission in patients with FM (385). Factors that trigger FM are frequently identifiable and include trauma, especially to the axial skeleton, surgery, infections, and active or chronic stress. Genetics also appears to play a role, as there is a higher incidence within families (384,386,387).

A multidisciplinary approach to treatment and an individualized treatment plan are important, as response to treatment varies widely. The current treatment protocols alleviate the peripheral sensitivity and diminish the central pain; they are palliation and not a cure. The goal of treatment is to maintain everyday activities and enhance quality of life. The best results are obtained using a combination of pharmacological and nonpharmacological therapies.

### Pharmacological

Evidence-based recommendations for the pharmacological management of pain from FM include anticonvulsants (pregabalin), tricyclic antidepressants (amitriptyline, desipramine), dual-action, SSNRIs (venlafaxine, duloxetine), and atypical analgesics (tramadol) as first-line medications in alleviating the pain from FM (388–393). These medications may be used in combination, as each may have a different mechanism of action. Current Food and Drug Administration (FDA) approval for treatment of FM includes Pregabalin up to 150 mg orally three times a day and duloxetine up to 60 mg orally twice a day. No evidence suggests the efficacy of corticosteroids, melatonin, NSAIDs, opioids, or thyroid hormone in the treatment of FM (394).

### Nonpharmacological

Nonpharmacological treatment includes patient education, exercise, and cognitive behavior therapy. Patients need to be aware that this is a chronic, but not life-threatening disorder and that the goal of treatment is to work with the physician and health care team to improve functional abilities and quality

of life. The relationship between physician and patient is likely to be long term, optimized with open lines of communication to discover the best treatment for each individual. There is high-quality evidence, based on meta-analysis, that supervised aerobic exercise training at prescribed levels has positive effects on physical function and feelings of well being in patients with FM (395). However, studies also show that compliance with exercise as a treatment is quite low in this patient population (396). Factors influencing the patient's ability to exercise or barriers to exercise should be addressed. Excessive or over-vigorous exercise programs tend to lead to pain, fatigue, and noncompliance; therefore, an individualized, slowly progressive aerobic exercise plan often decreases pain and fatigue while increasing a sense of well being with improved compliance. Cognitive behavior therapy may be helpful to manage the psychological aspects of FM and may help to manage stressors that trigger or increase symptoms. The reasons for this type of therapy should be fully understood by the patient to be a component of a multimodal approach to their pain (394–397).

Significant research remains to be done in terms of etiology and treatment of FM. In the meantime, the goal is to help patients maintain and improve their functional abilities, as well as enrich their quality of life.

### Low Back Pain

Low back pain episodically affects nearly 75% of the population in most industrial nations. It is estimated that 15% of the workforce is affected by back pain each year (9). Approximately 90% of these incidences of back pain resolve in 12 weeks or less. It is estimated that the 10% of these workers who develop chronic low back pain (remaining off work for 3 months or longer) are responsible for 80% of the cost (lost wages, compensation, medical expenses, etc.) (398,399).

Strategies to prevent acute low back pain from progressing to chronic low back pain include use of conservative intervention, return to work as soon as possible, or continue working at a job the worker is physically able to accomplish during the recuperation period and rapid adjudication of disabilities/compensation claims (76,77). Comprehensive prevention and diagnostic programs have been identified (121,400). An extensive review of randomized, controlled trials in industrial low back pain over the past 20 years has repeatedly shown methodological limitations for interventions (6,121,187,200,401–403). For additional information on rehabilitation of the patient with spinal pain, the reader is referred to Chapter 33.

## CONCLUSIONS

The clinical management of an individual with chronic pain is often most challenging and almost always a multifaceted problem. The diagnostic and clinical evaluation, detailed history of the pain report, assessment of the impact of pain on the patient, directed and comprehensive physical examination (to include the patient's functional capabilities, diagnostic procedures as necessary, as well as consideration for any comorbidities

ties in clinical management) need to be individualized. This should be done to appropriately address each patient's multifaceted problem in order to alleviate the pain and enhance the patient's quality of life and functional capabilities. A one-size-fits-all treatment plan for patients with chronic pain of a specific type is rarely effective. Periodic reexamination, review of treatment efficacy, and reevaluation of each individual's care plan are essential to minimize the pain and optimize the function in each individual. Concise, long-term documentation is important in the long-term management of patients with chronic pain so that treatment strategy can maintain direction in patients with complex disease process and can assist in the periodic review of the efficacy of the patient's treatment. Most chronic pain patients have been seen by numerous capable physicians without amelioration of their disease process. The task is to evaluate a multifaceted disease process and come up with a comprehensive and structured treatment program for optimal results.

# Spasticity and Muscle Overactivity as Components of the Upper Motor Neuron Syndrome

Spasticity is derived from the Greek word *spasticus*, which means “to pull.” It is a component of the upper motor neuron syndrome (UMNS), which is caused by a lesion proximal to the anterior horn cell; in the spinal cord, brainstem, or brain. It has both positive and negative components. Weakness, paralysis, and fatigue are the negative signs of the syndrome, whereas spasticity, athetosis, hyperreflexia, release of primitive reflexes, and dystonia are the positive. Hyperreflexia, spread of reflexes beyond muscles stimulated, hypertonicity, co-contraction, clonus, and rigidity are often seen in association with spasticity (1). Another word that can be used to describe the positive signs of the syndrome is muscle overactivity. The treatment team involved in the management of spasticity may find it one of the most challenging issues confronting them in the care of patients with neurologic disability. The goal of the treatment is to address this muscle overactivity with the fewest side effects and least exacerbation of the negative components of the UMNS.

## EPIDEMIOLOGY OF SPASTICITY

Clinicians treating neurological disorders are often confronted with the issue of spasticity and muscle overactivity. There is limited information regarding the prevalence and incidence of spasticity in various conditions. As expected, it depends on the etiology of the UMNS. In spinal cord injury (SCI), Maynard et al. (2) reported a prevalence of 65% to 78% and in 2004, Rizzo et al. (3) reported that 85% of patients with multiple sclerosis (MS) had some spasticity. This information may well be dated, as the introduction of newer agents to slow the progression of the illness may affect the incidence of spasticity that is seen in MS. Studies performed at varying time frames after stroke differ in the incidence of spasticity reported post stroke. A study assessing people 3 months after stroke revealed a prevalence of 19% and 35% in those with hemiplegia (4). On the other hand, a rate of 38% was reported at 1 year post stroke (5).

## NORMAL MOTOR FUNCTION AND CONTROL

### Requirements for an Effective Motor System

To facilitate the discussion of spasticity pathophysiology, it is useful to discuss normal motor control. To function effectively, the motor system must be able to integrate sensory feedback, control reflex activity, and coordinate volitional movement. It is critical for the controller to have information concerning the position of muscles and joints in addition to muscle velocity. It is also critical for the system to rapidly respond to external forces to control and respond to reflex activity and to initiate and stop motor activity. Feedback must exist among the many pathways that pass through the cortical, subcortical, brainstem, spinal cord, peripheral nerve, and muscle. The most distal unit involved in motor control is the motor unit, a part of the peripheral nervous system that is critical for control based on excitation and inhibition of muscle fibers.

### The Motor Unit

The motor unit was first described by Sherrington (6). It is comprised of an  $\alpha$  motor neuron and all of the muscle fibers that are innervated by it. Not all motor units are the same, as they differ in recruitment patterns and firing rates. This is a result of the different demands and purposes of individual motor units. The units also differ by the types of muscle fibers that comprise them. There are two major fiber types: type I and type II. Type I fibers are small, red, and oxidative, and they fatigue slowly. Motor unit function reflects the fibers that they contain. Motor units full of type I fibers are responsible for the baseline tonic muscle activity. Type II fibers, on the other hand, are large, white, and anaerobic. These muscles are more powerful and can deliver greater speed and velocity than type I; however, they can fatigue easily. These units are brought in to increase the force or speed of a contraction. Additional motor units are a hybrid of the two fiber types (7,8). When working properly, motor units fire with coordination of agonist and antagonist systems, normal patterns of recruitment and decrement (9). Katz and Pierrot-Deseilligny (10) reported

the problems that can be created by co-contraction of muscles and muscles firing out of phase or at angles different from their normal areas of activity. This loss of the normal recruitment and decruitment pattern may play a key role in spasticity.

### Normal Regulation of the Motor Unit

The motor control system uses a feedback loop, integrating information about muscle activity, position, and velocity. This enables the motor system to control and coordinate the stimulation of agonist and antagonist muscles around a joint. Critical information required by the control system includes muscle length, velocity, muscle tension, and joint position. This is mediated by a combination of immediate monosynaptic reflexes and more complicated higher-level control involving spinal and supraspinal polysynaptic activity. This activity can either increase or inhibit activity at the motor unit level. Units fire when the net excitation minus inhibition reaches threshold (8).

### Muscle Spindle and Golgi Tendon Organs

The muscle spindle plays a critical role in the provision of necessary information for proper motor control. It is attached in parallel to the main muscle mass, and it contains afferent type Ia and II fibers that communicate information concerning position and rate of change of a muscle to the spinal column. The  $\gamma$  motor neuron is an integral component of the muscle spindle. During normal motor function, the  $\gamma$  motor unit coactivates with the  $\alpha$  motor neuron and maintains the spindle tension and efficiency (8). Were it not for the  $\gamma$  motor neuron, the muscle spindle would be unable to provide accurate information throughout the muscle's range of motion (ROM), as the spindle would be under less tension when the muscle contracts. This is analogous to a volleyball net being supported by two poles. The muscle contracting would be similar to the poles being brought closer together.

The Golgi tendon organs also play an important role in coordinating muscle activity. During normal movement the stretch reflex, which is mediated by the firing of the Ia afferent fibers, must be suppressed to allow full movement about the joint. This reflex is monosynaptic and mediated by the Ia afferents and is triggered when a sudden stretch is applied to a muscle, such as tapping on the knee. Some suppression of muscle activity is mediated through the Golgi tendon organs. Found within the muscle tendons, through the Ib fibers and their related interneurons, the Golgi tendon organs limit muscle contraction by facilitating antagonists and inhibiting agonists. Thus, they serve to impose a ceiling effect on muscle contraction and prevent musculotendinous injury (11).

### Spinal Interneurons

The spinal interneurons play a critical role in normal motor control and spasticity. The effects of the Ia and Ib fibers mentioned earlier are often mediated through and with the help of interneurons called Ia and Ib interneurons, respectively. Other interneurons, including the Renshaw cell and the propriospinal interneurons, are also an important part of the control process.

As mentioned earlier, the Golgi tendon organs generate a ceiling effect for maximum muscle tension. The Ib afferents from these organs connect to their respective Ib interneurons. These interneurons also receive supra- and propriospinal influences from above that facilitate antagonists and inhibit the firing of agonist muscles (8,10). The type Ia interneurons receive activation from the type Ia neurons from the muscle spindle. When activated, the Ia interneurons facilitate agonist activity and reciprocally inhibit antagonist muscles, preventing the futility of co-contraction. Ia interneurons are also under supraspinal influence, and this plays a critical role in strengthening of reciprocal inhibition by the type Ia interneuron. The loss of supraspinal influence on the Ia interneurons plays a critical role in co-contraction and cerebral origin spasticity (12).

The process of recurrent inhibition involves the Renshaw cell, which receives input directly from the  $\alpha$  motor neuron. This process shuts off agonist activity by its direct effect on the  $\alpha$  motor neuron, in addition to facilitation of antagonist function mediated via the antagonist muscle's Ia interneuron (13). Tight motor control requires the function of the Renshaw circuit, and a loss of its function may greatly compromise movements (10). Like many other neurons, spinal and supraspinal input influence Renshaw cell function. Renshaw cell inhibition is increased in SCI (14).

### Supraspinal Influences

Supraspinal influences play a major role in both volitional movement and the pathophysiology of spasticity. Rothwell et al. (15) demonstrated corticomotorneuronal pathways. Originating from the primary motor cortex, the corticomotorneuronal pathways are specific for specialized coordinated functions such as truncal balance or initiation of fine coordinated hand movements. Loss of these fibers leads to a functional deficit more than to spasticity. Reducing tone from the hands may improve passive and gross hand function but may not greatly improve fine movement (16).

The corticospinal tract is the major motor tract and originates from many areas within the brain. These include the extrapyramidal cells from the prefrontal region, the supplementary motor region, the cingulate gyrus, and the postcentral gyrus of the parietal lobe. The pontine medial reticulospinal and lateral vestibulospinal tracts are the main extensor pathways within the brain. The pontine system facilitates the  $\alpha$  and  $\gamma$  motor neurons of the extensors of the limb muscles with some input into the system from the sensorimotor cortex. The lateral vestibular tract is located in the ventromedial portion of the cord and terminates at the spinal cord motor neurons. Stimulating the lateral vestibular tract affects the motor neurons of the flexor muscles differently from the extensors, with the  $\alpha$  and  $\gamma$  motor neurons of the flexors inhibited and those of the extensors facilitated. The nucleus of the cerebellum also has an excitatory influence on extensor pathways (17).

Several pathways facilitate flexion. The medullary lateral reticular formation (MLRF) inhibits extensor pathways. The cortex facilitates its action, and cortical injury can lead to

net overactivity of the lower-extremity extensor system. The MLRF demonstrates its effect through its connections to the motor neurons, type Ia interneurons, and type Ib system. In cats, the corticospinal, corticoreticulospinal, and corticorubrospinal, all show significant flexor facilitation. Through interneurons, the corticorubrospinal tract excites flexor motor neurons and inhibits extensors. In addition, the medullary reticulospinal tract is a predominant part of a largely flexor-oriented system (18).

## PATHOPHYSIOLOGY OF SPASTICITY

### Origin of Spasticity

So from where does spasticity come? Dietz and Berger (19) have suggested that intrinsic properties of the muscle itself could explain the changes seen with spasticity. However, Nielsen et al. (20) feel that the term spasticity should only be used when the disorder is a result of “alteration of central processing of sensory input and to exclude structural changes in the muscles.” Based on work from animal models, the concept of “gamma rigidity” was raised. This concept states that through overfiring of the  $\gamma$  motor neuron, the spindle would be too taut and the Ia interneurons would be hyperexcitable. Efforts at identifying this with microneurography failed to confirm this hypothesis (21). Delwaide (22) felt that spasticity resulted from a loss of descending, facilitatory, inhibitory influences that act on Ia interneuron inhibition. In other words, reciprocal inhibition mediated through the Ia interneuron inhibition requires facilitation from higher centers. With injury to the central nervous system (CNS), the interneuron is unable to shut off antagonist muscles firing, with resultant increased velocity-dependent resistance to movement. The concept of a hyperexcitable motor neuronal pool has also been recently raised. In essence, these neurons would be hypervigilant and initiation of firing would occur with less excitation. This may result from a loss of tonic inhibition secondary to a loss of supraspinal influences. Some have expressed the belief that the ionic properties of the membrane itself are changed as well. Other theories that may explain spasticity include central collateral sprouting (23), presynaptic disinhibition (22), and denervation hypersensitivity (24). Neurotransmitters may also play some role in spasticity; some suspects include serotonin and substance P. In animal literature, serotonin has been noted to prolong responses and facilitate extensor responses (25). In general, no singular theory has been able to fully explain the pathophysiology of spasticity.

### Other Muscle Overactivities Seen in the UMNS

There are numerous types of muscle overactivity that result from the UMNS that require treatment. As Sheean (26) stated in his excellent review article, the different components are commonly lumped under the term spasticity. As a result, the word is often used generically for muscle over activity from the UMNS. It is important to differentiate them.

In his article, Sheean stressed the importance of understanding the different components of the UMNS and how it may result in different treatment approaches and results. Sheean divides the different components of the UMNS into three distinct categories based on their underlying etiology: (a) spinal reflexes (stretch, nociceptive and cutaneous), (b) efferent drives that are not totally dependent on afferent feedback from the periphery, and (c) disorders of voluntary muscle movement.

As a result of damage to the CNS, there is abnormal processing of spinal reflexes which results in many of the positive components of the UMNS. These reflexes are dependent on afferent feedback from the periphery including muscle stretch, pain or stimulation of the skin. The increase in stretch reflexes falls into this first category and includes tonic (baseline tone) and phasic (from sudden stretch e.g., deep tendon reflexes [DTRs] and spasticity) responses. Other related components include clonus, flexor reflex afferents that result from noxious stimulation and cutaneous reflexes such as the Babinski.

In the second category, Sheean included spastic dystonia and associated reactions. Spastic dystonia is a term that was created by Denny-Brown (27) to describe his observation that some of the spinal cord injured cats held their limbs in a flexed position. The position of the cats' limbs was not a result of a stretch and therefore was not a result of a reflex activity. This was even more strongly demonstrated when the posture remained after the dorsal root was transected. The only explanation that he could find to account for the observation is a supraspinal efferent drive to the motor neuron. The commonly seen clinical scenario that corresponds to Denny-Brown's cat model is the stroke patient whose arm rests in a flexed position. Associated reactions are another example of a positive UMNS that results from efferent supraspinal stimulation to the motor neuron. This is often seen when a person's arm gets progressively higher when he or she tries to push up from a chair or walk a distance. It appears to be related to the amount of effort that the person is exerting and/or the severity of the tone in the extremity (26). One theory regarding the etiology of this phenomenon is an inability to stop the spread of muscle activity. Treating this problem may prevent a person from being thrown off balance, thus facilitating transfers and/or mobility. An important clinical point is that this disorder could be resistant to a treatment that reduces sensory afferent input such as a dorsal root rhizotomy (DRR).

The third category is disorders of voluntary movement. A disturbance in reciprocal inhibition fits this category, as the prevention of pathological reciprocal inhibition is an important component of normal motor control. In the normal state, the type Ia interneuron receives input from the spindle-based Ia neuron and with facilitation from above is supportive of agonist activity and inhibits antagonist firing (12). Two clinical examples of this normal activity is the relaxation of the elbow flexors during attempted elbow extension and the relaxation of the plantar flexors during attempted dorsal flexion.

**TABLE 50.1 Sample Passive and Active Goals**

Passive	Active
Improved hygiene	Improvement of transfers
Ease of care	Improvement in ADLs
Positioning	Improved mobility
Facilitate casting or splinting	Decrease spasms
Reduce pain	Release inhibition of antagonists
Improvement of orthotic fit	Reduce contraction during voluntary movement
Reducing difficulty of donning orthotic	Improvement of balance by blocking associated reaction
Healing of decubitus ulcer	Improvement in foot position during stance phase of gait
Ease of dressing	Easier straight cathing

The authors have chosen these movements because they are commonly affected by pathological reciprocal inhibition as a result of the UMNS. Sheean (26) spoke about two subtypes of this condition. In the first subtype, the inhibition is reduced while in the second, it is increased. When a person tries to extend his or her elbow but contraction of the elbow flexors prevents, slows or at the least makes the movement more difficult, this may well be as a result of reduced reciprocal inhibition. Possible etiologies of this pathology include reflex (tonic and phasic) activity of the elbow flexors or simultaneous activation of the motor neurons of the flexors and extensors. The second type of reciprocal inhibition is that of increased reciprocal inhibition. This is commonly seen in the person who has the ability to dorsi-flex the ankle but is unable to do during attempted ambulation because the reciprocal inhibition generated by pathologic plantar flexors inhibits the tibialis

anterior activation. By reducing these muscle overactivities, there is a reasonable likelihood of increasing volitional firing of the antagonist muscle that may improve volitional function. The importance of recognizing these conditions cannot be overemphasized.

## MANAGEMENT OF SPASTICITY AND THE UMNS

An integrated team is required to successfully manage spasticity. Under the direction of a physician skilled in the management of spasticity, the team should be able to deliver the entire continuum of services. The remainder of this chapter addresses the indications and benefits of the different treatment modalities (Table 50-1). How do clinicians decide what treatment to offer? Often the question is answered by the skills of the treating clinician, in that a man with a hammer sees everything as a nail. A physician skilled in chemoneurolysis is far more likely to perform a nerve block than one less comfortable with the procedure. Physicians may be more inclined to prescribe an oral pharmacologic agent than to prescribe serial casting or splinting. Therefore, it is important for the treatment team to communicate effectively and access needed surgical consultations as appropriate. Of note, not all spasticity is dysfunctional. Some women with spasticity use their elbow flexor tone to hold their pocketbooks, whereas lower-extremity tone may assist in transfers, standing, and ambulation. Optimizing function should be the primary outcome parameter in the treatment of spasticity. To maximize quality of life improvements for patients undergoing spasticity management, the entire treatment team must monitor the efficacy and adverse effects of spasticity interventions and adjust treatment accordingly (Table 50-2).

**TABLE 50.2 Commonly Used Oral Medications**

Medication	Daily Dosage (Range)	Mechanism of Action	Comments
Baclofen	10–300 mg	Presynaptic inhibition of GABA <sub>B</sub> receptors. Is active both presynaptically and postsynaptically. Hyperpolarizes cell membrane	Risk of withdrawal seizures and hallucinations. Dose must be adjusted with renal disease
Diazepam	4–60 mg	Facilitates postsynaptic effects of GABA <sub>A</sub> by opening chloride channels in membranes resulting in increased presynaptic inhibition secondary to hyperpolarization	Oldest class of medications used for spasticity that is still in common use. Can have very long half-life
Dantrolene	25–400 mg	Interferes with calcium release from sarcoplasmic reticulum	Only truly peripherally acting oral agent. LFTs must be watched carefully
Clonidine	Oral 0.05 mg bid—0.4 mg/d or 1–6 patch/wk	$\alpha_2$ Agonist. Decreases tonic facilitation via locus coeruleus and in spinal cord enhances presynaptic inhibition	Primary use in SCI population. Theoretical limitation to use in ABI secondary to interference with recovery
Tizanidine	1–36 mg	$\alpha_2$ Agonist. Blocks release of excitatory neurotransmitters and facilitates inhibitory neurotransmitters. Antinociceptive and reduces spinal reflexes	Now available in 2 and 4 mg tablets. Slow titration reduces sedation side effect that is major limiting factor

## Functional Goals Should be the Target for Treatments

Spasticity and the UMNS are a result overall of an irreversible process within the CNS. Treatment decisions should be made based on the functional limitations imposed by spasticity and the UMNS, neither of which represents an independent disease state. Specific impairments or functional deficits such as pain, problems with position, hygiene, or mobility are the specific issues that therapy should address. Gans and Glenn (1) divided treatment goals into two categories. The first is the management of passive function, such as reduction of pain, positioning, hygiene, splint wearing, and prevention of contracture. The second is related to active functional activities; as they described it, “Diminished capacity of the patient to accomplish useful work with the motor system.” The goals of these treatment interventions are to improve volitional purposeful movement. Some examples include unmasking functional movement that is inhibited by antagonist spasticity, improving transfers, ambulation, and performance of activities of daily living (ADLs).

## Treatment Options

### Reduction of Noxious Stimulation

The first step in any program to manage spasticity is the reduction of noxious stimulation. Spasticity and muscle overactivity have been shown to be increased as a result of this input (28). Stimulation of the flexor reflex afferents may lead to an increase in pathologic activity (29). The term *noxious stimulation* encompasses a wide variety of conditions such as a pressure ulcer, ingrown toenail, contracture, kinked catheter, urolithiasis, urinary tract infection, deep venous thrombosis (DVT), heterotopic ossification, fecal impaction, sepsis, and fracture. This is just a partial list. Addressing these conditions should generally be the first approach in spasticity management.

### Positioning

Proper positioning is an important component of spasticity management. Poor positioning can result in an increase in spasticity and in decreased ROM, contractures, increased noxious stimulation, pain, and exacerbation of a vicious cycle that can lead to worsening spasticity (30). This is especially true in the ICU and acute hospital (28). Proper goals for a positioning program include improvement in body alignment and greater symmetry. Benefits include easing of nursing care, facilitation of therapy, and maximization of a patient’s function. Postures that should be avoided include a leg scissoring posture (bilateral hip extension, adduction, internal rotation), windswept position (hip flexion, abduction, external rotation on one side and relative hip extension, adduction, and internal rotation on the other), and frog-leg position, which can exacerbate the spasticity. Positioning is also important in the wheelchair. Tone can be minimized by placing the patient with the hips and knees at 90 degrees and by maintaining good torso position (30). While its full implication for treatment has not yet been clarified, the joint angle position during assessment of spasticity contributes to the measurement of both tone and reflexive action at the ankle and elbow joints (31,32).

## Stretch and Casting

The UMNS causes muscle shortening for several reasons. One reason is the immobilization of paralyzed muscles in shortened positions. This resultant decrease in longitudinal tension (muscle unloading) can predispose to contracture. Immobilization can also cause a reduction in protein synthesis in immobilized muscles, thus promoting atrophy (33). Spasticity and muscle overactivity also play a part in muscle shortening (34). This can in turn result in an increase in spindle activity and sensitivity (35). Gracies et al. (28) have discussed the need to promote the commencement of stretch early in the treatment of any neurologic condition. Stretch has the advantage of being a focal treatment that can combat the development of the previously mentioned muscle shortening and increase in spindle sensitivity (33).

Schmit et al. (36) have demonstrated the benefit of a relatively brief stretch in the management of spasticity. However, the benefit is short-lived, as the tone returns after a single contraction (37). Therefore, stretch needs to be applied for a longer period of time to have potential functional benefit. A study involving the use of a Lycra garment that provided a stretch of 3 hours demonstrated both an improvement in spasticity and good patient tolerance (38). Stretch has been shown to be useful in volitional movement in both agonist (39) and antagonist muscles (40). Finally, in a nonblinded convenience sample, Selles et al. (41) reported that a 4-week program utilizing a device to deliver “intelligent stretch” was effective in treating spasticity and contracture in stroke patients as measured by joint properties, gaits speed, and subjective reporting. In summary, stretching activities have the advantage of being a local treatment, with limited risk that has demonstrated proven effect in the management of spasticity.

Chronic stretch via casting or splints changes reflexive activity and reduces the stretch reflex (42–44). Serial casting is defined as the use of successive casts to treat increased tone and contractures. Some of the original work regarding the effectiveness of serial casting in the management of spasticity and contracture comes from the group at Rancho Los Amigos (45), which reported their treatment of the lower extremities in 42 patients with a brain injury. It is not definitely known how often to change serial casts. Pohl’s group (46) performed a retrospective chart review investigating the differences between changing casts every 1 to 4 days versus 5 to 7 days. They found that at 1 month the changes in ROM between the two groups were comparable, but the complication rates were very different. The group with casts changed every 5 to 7 days had a complication rate of over 29% while the group with more frequent changes only had a rate approaching 9%. Almost 13% of the casting efforts had to be discontinued secondary to complications. A review of the literature discussing upper-extremity casting was unable to demonstrate a definitive answer supporting or rejecting casting as a treatment. Using casting to facilitate the action of chemical denervation has been addressed in several studies. Some preliminary studies have shown that using casting in combination with botulinum toxin treatment has increased the treatment effect in the stroke

(47) and cerebral palsy (CP) populations (48). The duration of the effect of serial and bivalve casting has been addressed in several studies. One study demonstrated that the effect was maintained 1 month after its use was discontinued (46). Its use in combination with botulinum toxin has been studied. In summary, casting can be considered a beneficial treatment option in the management of spasticity and contractures and is commonly used in programs with experienced clinicians; definitive recommendations regarding its use cannot be made at this time.

### Physical Modalities

Physical modalities can play a role in the management of spasticity. Like stretching, they have the benefit of being benign interventions with localized treatment benefits. The use of these agents will most likely remain as part of a spasticity treatment program. Used correctly, the physical modalities can have an important role in spasticity management.

Cooling of muscles is beneficial in the management of spasticity (49,50). It both inhibits the monosynaptic stretch reflexes and lowers receptor sensitivity after it is removed (51,52). Cooling can be used in different ways. The quick icing technique, with ice applied with a light striking movement, results in facilitation of  $\alpha$  and  $\gamma$  motor neurons and is used to facilitate antagonist function (53), whereas prolonged cooling can result in decreased conduction velocity and a reduction in the maximal motor complex motor action potential (49,54–56). The issue of cooling and muscle elasticity was addressed in a study that found a 3% to 10% decrease in elastic stiffness after a 30-minute ice cooling over the calf muscles (56). However, the effect lasted less than 1 hour. Another method of cooling delivery includes the use of an evaporating spray, such as ethyl chloride (57). With their short duration of action, the cooling modalities may have their greatest utility by therapist to reduce muscle overactivity to allow other therapeutic interventions.

Heat is another modality that can be applied in various forms. Ultrasound, paraffin, fluidotherapy, superficial heat, and whirlpool are some of the most common ways heat is applied. Heat's effect has a short duration (58), and, like cold, its application should be followed immediately by stretching and exercise. The effects of heat on spasticity have been studied in only a limited way. Its major effect seems to be related to an increase in elasticity that may assist in stretching activities (59).

Deeper heating modalities have also been used in the management of spasticity. Wessling et al. (60) demonstrated that 1.5 W/cm<sup>2</sup> in combination with stretch resulted in a 20% greater distensibility than stretch alone.

### Electrical Stimulation

Electrical stimulation is another modality that can help spasticity management. Transcutaneous electrical nerve stimulation (TENS) units have been shown to be useful in the management of pain. Through its nociceptive action and resultant reduction in pain, it was thought to reduce spasticity. Specifically, by reducing the flexor reflex afferents that are facilitated by

nociceptive stimulation (29), Bajd et al. (61) demonstrated a reduction in SCI-related spasticity in three of six patients in a dermatomal pattern, while a group applying TENS in an acupuncture method demonstrated a substantial reduction in spasticity that was partially reversed by coadministration of naloxone (62). Other potential mechanisms of action for spasticity reduction include inhibition or fatiguing of spastic muscles and possible activation of antagonist muscles through the Ia interneurons (63).

Numerous electrical stimulation devices are now being used to facilitate motor recovery secondary to CNS pathology. While the literature concerning these devices deals primarily with recovery; some information regarding their effect on spasticity has been reported. A single-blinded study performed in 2005 evaluated the effect of functional electrical stimulation (FES) on acute stroke patients. This study reported that 15 sessions of 30 minutes of FES administered in a reciprocal fashion to imitate normal gait resulted in improved ambulation and spasticity as measured by the Composite Spasticity Scale (64). Chen et al. (65) tested the effect of surface stimulation on the gastrocnemius of chronic stroke patients showing electrophysiological changes and a trend to a reduced ankle Ashworth score. Aydin's group (66) provided evidence that TENS may be of value as an adjunct for spasticity management in the stroke population. A recent study (67) on stroke patients demonstrated that ankle plantar flexor tone could be reduced with a combination of Bobath techniques and 9 minutes of stimulation to the dorsal flexor muscles. Some limited results have also been demonstrated with the use of electrical stimulation in people with CP (68,69). Finally, Krause et al. (70) demonstrated that an FES bike was beneficial in the management of spasticity secondary to MS.

### Massage

Massage is a therapy that is often desired by patients and their families. However, a review of the literature does not reveal any strong scientific evidence that supports its efficacy and utility (53,71,72).

### Pharmacologic Treatments

Four common methods are currently being used in the delivery of pharmacologic agents. The oldest method is delivery through the enteral system, either by mouth or via gastrostomy tube. Agents such as baclofen, benzodiazepines, or tizanidine are delivered in this fashion. These agents undergo systemic absorption and demonstrate an effect throughout the entire body. A second method, which is closely related to enteral delivery, is the use of a transdermal system. An example of this is Catapres TTS. Medications administered in this fashion are also absorbed systemically and demonstrate their effects throughout the body. Transdermal systems differ from the enteral methods by having a more steady-state blood drug level throughout the day with less fluctuation. Intrathecal administration of active agents is a third method of drug delivery. By placing the medications closer to their site of action, systemic side effects are reduced and clinical efficacy is obtained

with lower total doses. Baclofen, morphine, and clonidine are some of the more common medications that are delivered in this manner. Local injection of chemodenervation agents is the fourth method of drug delivery. Agents such as phenol and ethanol classically and now in the last decade the botulinum toxin products fall in this category. This last mode of administration is the best choice for treating a focal issue with a minimum of systemic effects, though some systemic absorption is still detectable.

### **Specific Components of the Pharmacologic Decision Process**

Many factors contribute to the decision of which pharmacologic agent to use in a particular patient. A partial list includes etiology, time since onset of medical issue, prognosis, access to medical services, personal support system, concurrent medical problems, cognitive status, and financial resources. All these items are important. A brilliantly planned intervention that the patient cannot afford is of no value. Similarly, an aggressive outpatient therapy program is of no value if transportation cannot be obtained for the patient.

#### ***Etiology***

Spasticity may present similarly despite originating from different etiologies. Nonetheless, responsiveness to various treatment interventions may vary depending on the etiology. As an example, enteral pharmacologic agents have been shown to be of great efficacy in the management of spasticity resulting from SCI or MS (73–77), whereas the benefit in spasticity caused by traumatic brain injury (TBI) or stroke is far less apparent. A further complicating factor in cerebral origin spasticity is the potential for impairment of recovery secondary to treatment (78), or a potentially intolerable cognitive side effect profile even when the agent may be effective (79).

#### ***Time Since Onset***

As a general rule, more aggressive spasticity interventions are tried later in the course of an event. Medications that may impair recovery are less likely to be used early on. For patients who have low-level functioning post TBI, physicians are less likely to prescribe sedating antispasticity agents. Phenol neurolysis is rarely used early in recovery, as the scarring of muscle and nerve and long duration of action may be undesirable in a recovering patient. Orthopedic interventions are almost never offered early on, as there needs to be stabilization of the neuromuscular structures before permanent surgical intervention. Relative to intrathecal baclofen (ITB), there is now some controversy as to what is considered too early. A recent report from France demonstrated that ITB may be beneficial for recalcitrant spasticity when initiated in the first month post injury (80).

#### ***Functional Prognosis***

When a patient's prognosis for motor and functional recovery is very guarded, this may lead clinicians to attempt more aggressive, permanent interventions such as a rhizotomy.

The need to facilitate care delivery with aggressive means of reducing spasticity may be preeminent over efforts to promote an unlikely recovery.

#### ***Support System***

The availability of social support may be an important factor in the management of spasticity. A number of questions should be considered. Can medication administration be supervised in the cognitively impaired patient? A family member or other caregiver may be critical for the physician to safely prescribe medications. Are supervision and assistance available for transportation to therapy or assistance in safe utilization of splinting devices? Will the patient be able to follow up for ITB pump refills or will there be the risk of withdrawal if the patient fails to follow up for pump refills?

#### ***Cognitive Status***

It is important to assess a patient's cognitive ability when prescribing treatment. The clinician must address the patient's ability to be compliant and remain safe while using a treatment modality. Will the patient be noncompliant with a medication and risk withdrawal seizures? Will there be a risk of skin breakdown with the use of a splint or serial cast?

#### ***Concurrent Medical Problems***

The overall medical condition of the patient being treated must be considered. Patients with hypotension, syncope, balance disturbances, or ataxia may be unable to tolerate the side effect profile of certain agents. Would an oral agent cause hypotension and resultant syncope, exacerbate ataxia, coordination, or balance disturbance? Does the patient have chronic infections that would increase the risk of development of an infection with an indwelling catheter or ITB system?

#### ***Distribution of Spasticity***

How diffuse is the area that needs treatment? Is there a focal or segmental area that needs treatment or is spasticity distributed diffusely throughout the entire body? If there are only discrete regions or only the discrete regions need to be treated even in the midst of diffuse spasticity, chemodenervation may be most appropriate. If the target condition is more systemic, then treatment that is more global will be necessary.

#### ***Financial Issues***

ITB and botulinum toxin injections cost thousands of dollars. Paying out of pocket for some modalities is not realistic and the physician, patient, and family have to utilize third-party payers. Some insurance companies are requiring trials with less expensive agents such as oral antispasticity agents before approving toxin injections. Clinicians are often required to justify their decisions and recommendations.

### **Oral and Transdermal Medications**

Oral and transdermal medications are commonly used in the treatment of spasticity. Table 50-3 summarizes the usage of these medications.

**TABLE 50.3** Comparisons of Different Treatment Modalities for Spasticity

Spasticity Treatment	Indications	Advantages	Disadvantages
Therapeutic modalities	Used by therapist for early management and facilitation of chemodenervation	Minimal side effects	Short duration of effect
Oral medications	Generalized tone, spasms, no focal region of spasticity	Systemic administration. Can treat large area of spasticity	Systemic side effects such as sedation, metabolic load
Botulinum toxins	Focal area of spasticity	Can treat spastic area without systemic side effects	Expensive, 3-mo duration when procedure needs to be repeated
Phenol	Focal area of spasticity	Can treat spastic area without systemic side effects. Much cheaper than Botulinum toxins and longer duration	Requires considerable skill of injector, risk of dysesthesias, painful procedure
Orthopedics procedure	Potential improvement in passive or active ADLs. Stable neurologically	Can be long-term repair	Surgical risk, loss of motor strength
ITB	Significant tone not adequately treated by other modalities	Baclofen gets to spinal cord with minimal systemic absorption	Surgical procedure, pump and catheter will eventually need replacement, high cost, risk of catheter dislodgement or kink

### Benzodiazepines

The benzodiazepines were the first agents used in the management of spasticity. Of this class, diazepam (Valium) is most commonly used. Other agents include clorazepate (Tranxene) and clonazepam (Klonopin). Ketazolam (Loftran) is another benzodiazepine that has been trialed for spasticity and is available in Canada but not in the United States (81). The benzodiazepines' mechanism of action is central in origin, acting on the brainstem reticular formation and spinal polysynaptic pathways (82). The benzodiazepines demonstrate their effect via GABA<sub>A</sub> (γ-aminobutyric acid), which opens membrane Cl<sup>-</sup> channels with resultant hyperpolarization. The net effect is a reduction of monosynaptic and polysynaptic reflexes and an increase in presynaptic inhibition (81).

Initial dosing for diazepam is 2 mg bid or 5 mg at bedtime, with a gradual titration upward to a maximum of 60 mg/day for adults. Benzodiazepines are well absorbed after enteral administration and peak at 1 hour. There is a relatively long half-life for benzodiazepines when accounting for its active metabolites, which ranges between 20 and 80 hours. The side effect profile can be quite problematic, including problems with addiction and withdrawal, ataxia, weakness, cognitive impairment, memory dysfunction, poor coordination, fatigue, and CNS depression that can be potentiated by alcohol. Research with diazepam has demonstrated improvements in painful spasms, hyperreflexia, and passive ROM. Evidence concerning functional improvement is limited.

Clorazepate has been shown to have a more favorable side effect profile than diazepam. In clinical trials, it was noted to have fewer problems with sedation and memory (83,84). Its half-life is relatively short but its active metabolite, desmethyldiazepam, has a half-life of up to 70 hours. In obese patients, the half-life of clorazepate can extend beyond 200 hours (85). Doses of 5 mg bid have been used in clinical trials.

### Benzodiazepines in SCI

The greatest benefit for diazepam has been demonstrated in the SCI population. A double-blind crossover study with 22 patients with SCI-related spasticity demonstrated efficacy (86), whereas another study with 21 patients with MS or SCI showed that diazepam is superior to placebo in treating spasticity. Whether the benzodiazepines are better for complete or incomplete lesions is debatable. Whyte and Robinson (87) suggest that benzodiazepines are effective only for incomplete lesions, but this is still controversial (88,89). A survey performed at Veterans Administration SCI programs showed that 70% of prescribers routinely give benzodiazepines to their patients (90).

### Benzodiazepines in MS

Studies performed in patients with MS have compared the efficacy and side effect profiles of the benzodiazepines versus baclofen. The two agents had very comparable efficacies and tolerance. Sedation was found more often with the benzodiazepines, whereas the baclofen group had a more varied list of side effects (91–93).

### Benzodiazepines in Acquired Brain Injury (ABI)

Benzodiazepines are rarely used in the ABI population because of their potential for cognitive side effects as well as their potential to compromise motor recovery (78).

### Benzodiazepines in CP

Few studies are available concerning benzodiazepine use in the CP population. Engle (94) conducted a double-blind crossover study that demonstrated the efficacy of diazepam in the management of patients with CP. However, determining whether the improvements were behavioral in origin was questionable. Mathew and Mathew (95) demonstrated in a

placebo-controlled study the efficacy of bedtime diazepam administration in improving ADLs and reducing the burden of child care in children with CP without significant adverse side effects. Nogen (96) studied diazepam and dantrolene in patients with CP and found benefit with both agents. Cruikshank and Eunson reported on the utility of intravenous diazepam in their management of planned discontinuation of ITB in three cases of individuals with CP (97).

### **Baclofen**

Baclofen (Lioresal) is another agent that mediates its activity through the GABA system. It differs from the benzodiazepines by mediating its effect via GABA<sub>B</sub> rather than by GABA<sub>A</sub> and is active both presynaptically and postsynaptically. Its action presynaptically is to bind to the GABA interneuron, where it causes hyperpolarization of the membrane that prevents the influx of calcium and resultant release of neurotransmitter. When it binds postsynaptically, it hyperpolarizes the cell membrane by acting on the Ia afferents. As a result, baclofen is inhibitory on both the monosynaptic and polysynaptic reflex pathways. Baclofen is eliminated via the kidney, and its half-life is roughly 3.5 hours (81).

When initiating treatment, 5 mg bid to tid is recommended, and this can be increased 5 to 10 mg/day/week. The Physician's Desk Reference suggests a maximum dose of 80 mg/day, but while not routinely recommended, doses as high as 300 mg/day have been used safely (81). Baclofen-related side effects reported include sedation, fatigue, weakness, nausea, dizziness, paresthesias, hallucinations, and lowering of seizure threshold. The patient is at greatest risk when the agent is abruptly discontinued, as hallucinations and withdrawal seizures have been reported (87). Since baclofen primarily undergoes renal clearance, dosing may need to be adjusted with kidney-related issues (98). When switching from oral to either IV or ITB administration, one must be wary of potential withdrawal-related issues. This is based on the efficiency of localization that results from IV or intrathecal dosing, as there is a relatively low dose of baclofen in the brain as compared with the lumbar cord region.

### **Baclofen in SCI and MS**

Much of the baclofen literature combines research on patients with SCI and MS; therefore it is appropriate to merge a discussion of baclofen in these populations, although some differences will be highlighted (73,98–101). Feldman et al. (100) reported that the use of baclofen in patients with MS demonstrated a significant reduction in spasticity as well as reducing painful flexor spasms. Flexor spasms in the SCI population also responded to baclofen administration (73,74,102–105). It is far more difficult to find studies that demonstrate functional improvement, given that investigations were unable to demonstrate improvements in ADLs and ambulation with administration of baclofen (102,104). Orsnes et al. (106) studied patients with MS treated with baclofen but again found no functional improvement. Nielsen et al. (107,108) studied the effect of oral baclofen on the soleus muscle. Treatment with

baclofen reduced ankle stiffness and increased soleus response latency. However, it also was found to increase the weakness in soleus function, which may explain the lack of functional improvement.

### **Baclofen in ABI**

There is limited literature that has noted positive effect with oral baclofen in the ABI (103,109,110). A double-blinded study in the elderly stroke population was discontinued because of treatment-related sedation (111).

### **Baclofen in CP**

Milla and Jackson (112) conducted the one blinded crossover trial in the CP literature that demonstrated efficacy. Actual functional benefits were not seen, but decreased scissoring and improvements in ROM were noted. The authors reported few side effects and recommended dosing of a total of 5 to 10 mg total per day in divided doses for children 2 to 7 years of age. A recent publication looked at the effect of 4 weeks of oral baclofen on ten children with CP. The authors looked at the effect of medication on neuromuscular activation and ankle plantar flexor torque. Neuromuscular activation was measured using surface electromyography (EMG) generated during maximal voluntary contraction to the M-wave during supramaximal electrical stimulation of the tibial nerve. They noted a statistically significant improvement in neuromuscular activation but this was not accompanied with isometric plantar flexion torque. The authors hypothesize that the agent may be beneficial in the facilitation of strength training (113); however, further work is needed to address this question.

### **Dantrolene Sodium**

Unlike many other agents, dantrolene (Dantrium) is an enteral medication that acts peripherally, at the level of the muscle itself. Its mechanism of action is to inhibit calcium release from the sarcoplasmic reticulum during muscle contraction. Rather than dampening neuronal activation, it reduces the strength of contraction. In addition to its action on the muscle extrafusal fibers, dantrolene reduces muscle spindle's sensitivity by acting on the  $\gamma$  motor neuron (71). Dantrolene's primary action is on fast-twitch fibers. Parameters affected by it include easier ROM and tone. Starting dose is 25 mg bid and can be increased weekly by 25 to 50 mg to a maximum of 400 mg/day (114). Dantrolene's enteral half-life is approximately 15 hours and is given bid to qid (81). Dantrolene's most well-known side effect is potential liver toxicity. However, overall this is a rare occurrence, with a rate of only 1.8% (115) when administered for more than 60 days. Even when discovered it is usually reversible. It is found most commonly in women over the age of 40, especially if they had been on high doses, greater than 300 mg for a long period of time (116). Fatal liver failure has been reported in 0.3% of those who received the medication. Therefore, it is critical for clinicians to follow liver function tests (LFT) when prescribing dantrolene. Blood tests should be performed weekly for the first month, monthly

for the remainder of the first year, and four times a year after that. In addition to liver toxicity, other problems associated with dantrolene include weakness, paresthesias, nausea, and diarrhea (81). Rare side effects also include anorexia, enuresis, visual disturbance, acnelike rash, inhibition of platelets, eosinophilic pleural effusion syndrome, and pericardial effusions (116,117). There has also been a single case report of a minimally conscious 43-year-old female with acontractility of the bladder (118).

### ***Dantrolene in SCI***

Since dantrolene is associated with weakness, there have been few trials reported with its use in SCI. An early study by Glass and Hannah (119) reported that it was more effective than diazepam in controlling spasticity but was associated with greater weakness. Studies have demonstrated improvements in ROM and tone but no functional improvement (120,121). Additionally, two cases are reported in the literature where SCI patients responded to dantrolene when treated for baclofen withdrawal (122,123). A recent 2006 Cochrane review failed to reveal any studies of dantrolene in SCI patients rigorous enough to meet the criteria (124).

### ***Dantrolene in MS***

There is limited literature describing the use of dantrolene in patients with MS. Again, this may well be due to a poor tolerance, given the undesirable side effect of additional muscle weakness. Two studies performed demonstrated improvement in tone and ROM. However, the benefits were outweighed by the clinical weakness found while on the medication (125,126). Its use in patients with MS cannot be recommended from the literature.

### ***Dantrolene in ABI***

Whyte and Robinson (87) have recommended dantrolene for use in the treatment of ABI-related spasticity. Chyatte et al. (127) reported on nine patients with stroke-related spasticity. Although they demonstrated no functional improvements in ADLs and mobility, they noted improved ROM, DTRs, and some upper-extremity function. Ketel and Kolb (128) reported that in their selected population of dantrolene responders, there was an exacerbation of spasticity accompanied by clinical deterioration when they were placed on placebo.

### ***Dantrolene in CP***

While reviewing the data concerning the use of dantrolene in patients with CP, Krach (129) reported on four studies that demonstrated good efficacy. Haslam et al. (130) reported decreases in DTRs and scissoring. Dosing in the pediatric population has been up to 12 mg/kg. Verrotti et al. (131) suggested that it could be efficacious when used in combination with diazepam and that it may be more effective than baclofen, with younger children demonstrating better tone reduction and older children showing improved motor movement.

## **Clonidine**

Clonidine (Catapres) is an imidazoline derivative that is primarily an antihypertensive agent. It is a central acting  $\alpha_2$ -adrenergic agonist that has been shown to demonstrate some efficacy in spasticity management, primarily in SCI. It peaks in 3 to 5 hours when taken orally and has a usual half-life of 5 to 19 hours, with an extended half-life of up to 40 hours in persons with renal impairment. Clonidine's clearance is primarily renal, with half of it first metabolized by the liver. Clonidine has two distinct mechanisms of action. First, it acts directly on the locus coeruleus and decreases tonic facilitation (81). Second, it also has a spinal mechanism, acting to enhance  $\alpha_2$ -mediated presynaptic inhibition (132–134). Clonidine doses as low as 0.1 mg orally are often effective in treating spasticity (133). A transdermal system that allows for more uniform blood levels and easier administration is also available. Side effects reported with clonidine include bradycardia, depression, lethargy, syncope, and hypotension (133,135). There is no literature to date describing clonidine use in patients with MS.

### ***Clonidine in SCI***

Two separate reports demonstrate clonidine's potential efficacy in the SCI population (136,137). Nance et al. (134) showed that resistance to stretch was reduced in her small series of four patients treated with 0.2 mg/day. Donovan et al. (132) reported on the use of clonidine as an adjunct to baclofen in spasticity management. They reported an overall 56% response rate, with improvements noted in persons with paraplegia and tetraplegia with complete and incomplete lesions. The authors reported that three patients who had been responsive had to be discontinued secondary to postural hypertension.

### ***Clonidine in CP***

Lubsch et al. (138) published a retrospective chart review of 87 children with the diagnosis of spasticity secondary to TBI or CP who were on either baclofen or clonidine. Eighty-six persons were taking baclofen and only 31 were taken clonidine. Eighty percent of the population studied included in this review had the diagnosis of CP, with the remaining having the diagnosis of TBI. The two populations were not analyzed separately in the paper which further limits its utility. The paper did report on the safety and tolerability of clonidine administration to children with CP in doses ranging from 0.025 to 3.6 mg/day.

### ***Clonidine in ABI***

Clonidine can impair motor recovery after ABI (78), thus making its use in these patients somewhat controversial. Several publications address clonidine use in ABI including a case report concerning brainstem origin spasticity (139) and a six-patient case series (140). The Lubsch study (138) mentioned above some very limited information on the use of clonidine in ABI. However, only 20% of the population was TBI and thus, the information for ABI is even more limited than for CP. Further work needs to be done to clarify clonidine's place as an antispasticity agent in this population before any evidence-based recommendations can be made.

### **Tizanidine**

Like clonidine, tizanidine (Zanaflex) is an imidazoline derivative with  $\alpha_2$ -agonist effects and is the newest, widely used antispasticity agent. Its onset is rapid, 1 hour, and it has a very short 2.5-hour half-life and may require frequent dosing. It is cleared via liver metabolism and then is excreted by the kidneys. One mechanism of action is mediated through its effect on neurotransmitters. Tizanidine blocks the release of the excitatory amino acids, glutamate, and aspartate, in addition to facilitating the inhibitory neurotransmitter glycine (81). Animal research reveals other potential mechanisms of action that include antinociceptive activity (141–143), in addition to an ability to reduce spinal cord reflex activity (141,144).

The side effects of tizanidine can be quite troubling, with close to 15% of participants discontinuing the medication during clinical trials due to side effects (145). Drowsiness is reported in up to 50% of patients on clinical trials (145–147). The work of Meythaler et al. (79) may be the most telling, as patients who were obtaining benefit from tizanidine's antispasticity effect were lowering the dose to limit the side effects, despite a lower clinical efficacy. Another major side effect is dry mouth (145–147), with up to 11% of people complaining of it. Other complaints included fatigue, dizziness and hypotension (148), muscle weakness, nausea, and vomiting. There is also a potential for liver damage, and LFT should be evaluated before medication initiation and at 1, 3, and 6 months after initiating treatment. Initial dosing begins at 2 to 4 mg before bedtime and can be increased to a maximum of 36 mg/day (81).

### ***Tizanidine in SCI***

Tizanidine has been well studied in patients with SCI (75,149), although a Cochrane review published in 2006 (124) was only able to demonstrate one trial that met its strict criteria. The trial demonstrated a significant reduction in spasticity and an early reduction in spasm frequency. No change in muscle strength was observed. There were also significantly more side effects reported in the tizanidine group than the placebo group (124). Other important points from the Cochrane review are that there was no evidence of benefit from any of the other oral agents that they reviewed. They also reported no evidence of functional benefit from tizanidine use, but that the side effects were tolerable. Overall, it has been shown to be effective with an acceptable side effect profile with no weakness noted. Tizanidine is considered safe and effective in this population.

### ***Tizanidine in MS***

Several studies have demonstrated the efficacy of tizanidine in patients with MS (145,147,150,151). In work from the U.K. Tizanidine Trial Group (152), an improvement in clonus and spasms was seen but not in tone or function. The work by Lapierre et al. (147) demonstrated improvement in clonus and DTRs, but again no functional changes could be detected. Two studies compared tizanidine to baclofen and revealed that tizanidine was as effective as baclofen and better tolerated (145,151).

### ***Tizanidine in ABI***

Despite being a relatively new agent, tizanidine has undergone its most rigorous testing in ABI and may turn out to be the most effective agent in these patients. Meythaler et al. (79) reported on a series of 17 patients treated with an escalating dose of tizanidine. When they had reached their maximal dose, the patients demonstrated statistically significant decreases in their upper- and lower-extremity Ashworth scores and lower-extremity spasm scores. The changes were not significant in upper-extremity spasms or any of the reflex scores. The side effect profile, especially sedation, was problematic. The original plan was to reach a dose of 36 mg by 4 weeks; however, the maximal dose reached was a mean of 25.2 mg/day. This was lowered by an average of 2 mg later in the trial when the patients were able to self-select dosing. Once again there was no evidence of improved function, with the FIM and the Craig Handicap Assessment and Reporting Technique (CHART) showing no change with treatment. Bes et al. (146) performed a study that compared tizanidine to diazepam in the management of patients with chronic spastic hemiplegia. They reached their maximal level for each medication by week 6, and they underwent evaluation at week 8. Improvements in nonfunctional measures such as duration of stretch and muscle contraction as well as reduction of clonus were noted with both agents. In regards to functional measures, the participants demonstrated statistically significant improvement only while on tizanidine, as noted in walking distance on flat ground. They also reported that tizanidine was better tolerated than diazepam. Two recent reviews (153,154) suggest the use of tizanidine in the management of ABI-related spasticity. However, the clinical utility is still somewhat unclear as demonstrated by Meythaler et al. (79). This belief is further supported by the conclusions of a double-blinded placebo-controlled clinical trial comparing tizanidine to placebo and botulinum toxin. The results did not support the use of tizanidine for the management of upper-extremity spasticity secondary to ABI. The results demonstrated a clear superiority for the toxin treatment, while the tizanidine group was not shown to be superior to placebo (155). A final concern that needs to be highlighted is that tizanidine, like clonidine, is a member of the imidazoline family. Therefore, it also has the potential to impair neurological recovery after ABI (78).

### ***Tizanidine in CP***

There are no clinical trials published in the English literature that have tested the use of tizanidine in the management of patients with CP. A review article reported that it can be safely used in this population if the tablets are divided (129). The fact that the drug is available in scored 2 and 4 mg tablets is especially beneficial for dosing in this population. A study from Russia (156) reported that a dose of 1 mg three times a day for children under 10 and 2 mg three times a day for older children had significant benefit. In a double-blinded placebo-controlled study, 0.05 mg/kg/day of tizanidine was compared to placebo over a 6-month time period. Statistically significant

differences between placebo and active drug were noted in regards to reflexes and tone (157). Given the limited amount of data for this patient population, further research is clearly needed.

### Other Medications

Since spasticity is a significant and recalcitrant problem, the list of medications that have been tried in its treatment is endless. It would be impossible to list them all. Instead the authors will mention a few medications that have potential benefit or are undergoing further investigation. Piracetam is a GABA and baclofen analog that is available in Europe and is used as a cognitive enhancer (81). In one well-designed study, Piracetam was tested against placebo in a double-blinded crossover trial. Patients demonstrated improved passive range, hand function, and ambulation with a minimal side effect profile (158). Gracies et al. (81) have recommended further evaluation.

The cannabinoids have been shown to have efficacy in neurologic populations and are currently under study (159,160). Specifically, improvements in spasticity have been seen in patients with MS or SCI, but with mixed results (116). Recently Collin et al. performed a double-blind placebo-controlled study over 6 weeks that compared placebo to whole plant cannabis-based medicine containing delta-9 tetrahydrocannabinol and cannabidiol. Significant improvements were obtained in the subjective measure and a trend toward significance in the Ashworth (161).

Gabapentin's potential in spasticity management has also been examined in several studies in patients with MS and SCI (162–166). These studies suggested that at doses of 400 mg tid, gabapentin reduced spasticity with a benign side effect profile. Similarly, an animal model study demonstrated that intraperitoneal injection of gabapentin in rats with SCI reduced spasticity over a 24 hour period. The authors hypothesized that the effect was likely mediated through its effect on glutamate (167). Another anticonvulsant tiagabine, a GABA analog, was noted to decrease spasticity in an open-label trial (168). In their evaluation of outcome, the investigators noted a 50% reduction in tone on the modified Ashworth score, improvement in strength, coordination, and ROM. Two newer anticonvulsant medications, levetiracetam and pregabalin have also shown some efficacy in reducing spasticity (169–172). A retrospective review of 22 patients with spasticity resulting from TBI, MS, or CP noted that 12 patients reported reduction in spasticity with pregabalin (172). Reports have also noted reduced phasic spasticity, or “spasms” with the use of levetiracetam. In one retrospective review featuring 12 patients with MS, a significant improvement was seen in the Penn spasm score, with three patients also noting a reduction in their neuropathic pain (171). Additionally, a case report noted the elimination of painful paroxysmal spasms in a patient with “stiff person” syndrome treated with levetiracetam (170). A trial has also been proposed to treat cramps and/or spasticity in patients with amyotrophic lateral sclerosis (169).

Finally, an open-label trial with the antinarcoticept drug modafinil was noted to improve spasticity in seven out of nine

patients with CP (173). A retrospective review of 30 patients with CP was conducted by the same investigators in 2004. Of the 30 patients, 23 reported diminished spasticity confirmed by increased joint mobility on physical exam; however, seven patients discontinued the medication because of an unacceptable side effect (174).

### Nerve Blocks, Motor Points and Chemical Denervation

It was mentioned earlier that when the symptoms of spasticity are focal, segmental, or regional, they can be treated with chemical neurolysis or chemical denervation (CD). In simple terms, chemical neurolysis is the process of a clinician treating spasticity and the UMNS by creating a lesion in the lower motor neuron. This is true regardless of the agent used, be it phenol, ethanol, or one of the botulinum toxins. Treatment goals are very straightforward: focally treat the area of muscle overactivity with the most beneficial side effect profile. First, here are some working definitions:

*Nerve block:* the application of a chemical to a nerve to impair function, either temporarily or permanently.

*Chemical neurolysis or chemodenervation:* a type of nerve block where there is actual destruction of nerve tissue to give a longer-lasting block.

*Motor point block:* the condition that occurs when a portion of a nerve lower down on the nerve trunk (hopefully, below the sensory branches) is blocked to create a motor block with a more limited sensory involvement (175).

What are some of the indications for chemical denervation? Autti-Ramo et al. (176) suggested that chemical denervation should be performed as part of the planning process before performing any orthopedic hand surgery. Chemical denervation can be beneficial when one chooses realistic, obtainable goals that will benefit from local intervention and includes the planning and performance of appropriate follow-up services. In a skilled clinician's hand, it can improve quality of life, reduce pain, increase ROM, break synergy patterns, and improve positioning and hygiene (175,177). In summary, chemical denervation is an effective intervention when used to treat a primarily focal region to address a problem caused by spasticity or another type of muscle overactivity, when the clinician has identified a clear goal of treatment (178).

### Agents Available for Chemical Denervation

Phenol and ethanol were the original agents used for chemical denervation. For chemical denervation, phenol should be used in a concentration of between 5% and 7%. At that concentration, it has an immediate anesthetic effect with a subsequent neurolytic effect that matures within 2 days. Ethanol, on the other hand, should be used in concentrations ranging from 45% to 100% to create a neurolytic effect. When comparing the two agents, one will find much more literature describing the use of phenol than alcohol. However, alcohol is less toxic and is easier for clinicians to obtain. The typical duration of effect of chemical denervation with either agent is between 3 and 9 months, but it may last as long as 12 to 18 months

(175,177). A study in 2005 by Cullu et al. found doxorubicin, an antitumoral agent that has recently been used for chemomyectomy, comparable to phenol in denervating skeletal muscle in rats. The investigators also noted that they were able to demonstrate a dose-dependent response in regards to denervation. While further study is needed, doxorubicin may represent another potential agent to be used for chemical denervation (179).

The development of the botulinum toxins provided another class of agents for chemical denervation. Currently, there are two different serotypes available commercially in the world; type A and type B. In 2008, the only type B formulation available anywhere is Solstice's Myobloc, which is sold under the name Neurobloc in Europe. There are numerous type A toxins available in the world; however, in 2008 the only one available in the United States is Botox (Allergan). There are several other type A toxins available worldwide. They are Dysport (Ipsen), Xeomin (Merz), Meditoxin/Neuronox (Medi-Tox), and CBTX-A/Prosigne (Lanzhou). The timeframe when any of these toxins will be available in America is not known and some may be already available at the time of this publication with the exception of Ipsen's Dysport which is already far

along in the process of FDA approval process. Botox has been available in the United States since 1989. Approved indications for Botox are blepharospasm, cervical dystonia, severe primary axillary hyperhidrosis, and cosmesis. Dysport and Xeomin are currently available in Europe. Meditoxin is available in Korea and its surrounding area, while CBTX-A is available in China and Brazil. Myobloc is approved for the treatment of cervical dystonia in adults in the United States.

### Mechanisms of Action for the Chemical Denervation Agents

Ethanol and phenol's action are mediated via their ability to denature protein. It is a crude process that can demonstrate an effect on both motor and sensory fibers, as the action is on the nerve itself (28,175,180). By contrast, the "botulinum toxins" act on the neuromuscular junction, where they inhibit the release but not the production of acetylcholine (ACh). ACh exocytosis is an important component of transmission at the neuromuscular junction with the soluble NSF attachment receptors (SNARE) complex critical for this process. The different toxins act as proteolytic agents at different sites of the SNARE complex (Fig. 50-1). Toxin A is active on Snap-25

**FIGURE 50-1.** Representation of SNARE complex at motor endplate. (Reproduced from Rowland LP. *NEJM*. 2002;347:382–383, with permission.)

(25-kD synaptosomal associated protein), whereas the B works on Synaptobrevin (also called VAMP), a protein attached to the Ach vesicle (181).

### Chemical Denervation with Phenol and Alcohol

Numerous publications describe the efficacy of phenol and alcohol chemical denervation. Khalili et al. (182), Halpern and Meelhuysen (183), DeLateur (184), and Awad (185) are just some of the original authors who published work showing the efficacy of phenol nerve blocks. Kong and Chua (186–188) have also demonstrated the efficacy of alcohol chemical denervation. This intervention has been used in various patient populations, including adult stroke, TBI, and CP (189–192).

Phenol and botulinum toxin may also be combined to treat individuals with more generalized spasticity. Gooch and Patton (193) demonstrated that this combination allowed more muscles to be treated with higher dosages in children with CP and other neurologic diseases, with minimal side effects. Additionally, Lee and Lee (194) recently reported utilizing ultrasound guidance to identify nerves during intraneural phenol injection with some increase in effective duration.

### Botulinum Toxin Therapy

Van Ermengem isolated the *Clostridium botulinum* bacteria after musicians developed a paralytic syndrome subsequent to eating raw ham at a wedding. There are seven serotype toxins produced by the bacteria, identified as A through G. At the time of the writing of this chapter, only two formulations of botulinum toxins were approved in the United States and commercially available here (type A, Botox; type B, Myobloc). At present, there are several formulations of the botulinum toxin's at different stages of the FDA's approval process, with Ipsen's Dysport the most advanced at the time of drafting this chapter. No botulinum toxin formulation is approved by the FDA for the treatment of spasticity, so at this time all treatment for this condition is off label (180).

All seven serotypes of botulinum toxin demonstrate their action at the neuromuscular junction, where they inhibit the release, but not the production, of Ach. This is accomplished via proteolytic cleavage of either a membrane or soluble protein of the system involved in Ach exocytosis called the (SNAP—soluble *N*-ethyl-maleimide sensitive factor attachment protein Receptor complex) SNARE complex. The SNARE complex has three critical components: synaptobrevin, a protein attached to the Ach vesicle, SNAP-25 (25-kD synaptosomal associated protein), and syntaxin, which are attached to the cell membrane. Toxins B, D, F, and G cleave synaptobrevin, whereas toxins A, C, and E cleave SNAP-25. Toxin C cleaves syntaxin as well. In contrast to phenol, botulinum toxin is transported to the nerve terminals and EMG or electrical localization is needed to identify only the muscles injected (71,72).

As biologic agents the toxins are measured by their potencies. A unit of toxin is defined as the LD<sub>50</sub> for an IP injection of toxin into an 18 GM Swiss-Webster Mouse. While all toxins' potencies are based on their effect on the mouse, they do not necessarily have corresponding potencies in human. The effect

on humans of 1 mouse unit of type A toxin is not the same as that of 1 mouse unit of type B toxin, as there are interspecies differences. There is no simple formula for converting a dose of type A toxin to a dose of type B toxin (71,72,180). There are also differences noted between the different type A toxins; however, it may be possible to determine ratios between the different A toxins. Wenzel et al. (195) reported that Botox was more potent than Dysport and that the ratio of dosing is 4 to 5/1. This is truly a very important issue when one is reviewing the literature or determining dosing for treatment.

### Clinical Uses of Botulinum Toxin

There are now over 50 reported therapeutic uses for botulinum toxin, with only a few of these approved by the FDA. Therefore, the majority of them can be described as off-label indications supported by randomized controlled trials include esophageal achalasia, essential tremors, palmar hyperhidrosis, headache, and chronic anal fissure (196,197). Other conditions that botulinum toxin has been used for include the treatment of urologic dysfunction (196,198–200), poststroke shoulder pain (201,202), and temporal mandibular disorders (203,204).

With the exception of the palmar hyperhidrosis and possibly headache, toxin injection addresses symptoms secondary to dysfunctional muscle contraction. Focal treatment with botulinum toxin is often preferred to generalized treatment with an oral medication that can be a source of systemic side effects (198,199,203,204). This is especially pertinent in patients where fatigue, dizziness, and hypotension need to be avoided, such as those with MS (198). Treatment with botulinum toxin in disorders where the symptoms are primarily caused by an overactive sphincter muscle may be seen as an attractive alternative to surgery due to its reversible nature. Examples include detrusor sphincter dyssynergia, chronic anal fissure, and esophageal achalasia (196,198,199).

Botulinum toxin treatment of spasticity in upper or lower extremities has been studied widely (205–221). One of the first studies demonstrating the utility of the botulinum toxins in the management of spasticity was performed by Snow et al. (222) who demonstrated the utility of toxin in the management of adductor spasticity secondary to MS. Its efficacy in TBI was first suggested in two studies performed by Yablon and Wilson's groups (223,224). Richardson et al. (225) reported on toxin A efficacy on patients after they failed conservative measures, demonstrated an improvement in parameters related to gait symmetry and velocity, and reported improvement in a mixed neurologic population 3 to 12 weeks after injection. Since then, multiple double-blind placebo-controlled studies have been performed investigating the use of botulinum toxin types A in the management of poststroke upper and lower limb spasticity (202,209,210,212,216,219,221,225, 226). A recently published study by Simpson et al. (227) demonstrated the efficacy of and the superiority of botulinum toxin A over the oral medication tizanidine in the management of upper-extremity spasticity secondary to ABI. Finally, a recently completed evidence-based review makes the recommendation

to consider the use of botulinum toxin A for the management of spasticity (228).

There have also been numerous studies that have addressed the efficacy of botulinum toxin A in the management of spasticity from various conditions including CP (205,206,211, 214,217,218,229,230), SCI (208), and MS (213,222,231). In general, the studies demonstrated a significant reduction in tone and improved ROM with some improvement in function (226). The only studies utilizing Myobloc to treat upper-extremity spasticity were unable to demonstrate significant improvement and reported numerous side effects (226,232). Repeated injection with botulinum toxin type A has been shown to be safe and efficacious (209,212,216).

### ***Botulinum Toxin Varieties***

**Botulinum Toxin A (Botox).** Allergan markets the toxin type A under the trade name Botox. In 1989, the toxin was licensed by the FDA as an orphan drug for the treatment of strabismus, hemifacial spasm, and blepharospasm. For years, Botox was the only botulinum toxin available in the United States. In its original formulation lot (79–11), the protein load was 25 ng per 100 units. In December 1997, a new formulation lot (BCB2024) with a protein load of only 5 ng per 100 units was introduced to replace the old toxin. These two toxins were noted to have similar clinical efficacies, but the lower protein load was believed to have the potential for lower antigenicity (233,234). The majority, but not all, of the studies performed with botulinum toxin A in the study of spasticity have been performed with the BCB2024 lot of Botox.

Botox comes packaged in a frozen lyophilized form of purified botulinum toxin A. It requires reconstitution with preservative-free saline prior to its use and should be used within 4 hours of reconstitution. The maximal therapeutic doses have been increasing as more information relative to safety has been obtained. Consensus guidelines from the NIH (235) suggested using maximum doses of 400 units in adults. Experienced clinicians have been pushing doses higher to improve clinical effect despite the above caveat. There still is a wide window for the risk-benefit ratio even if higher doses are used. For the primate, a lethal dose is 40 units/kg, or roughly 3,000 units for a 70-kg man (236).

**Botulinum Type A (Dysport).** Dysport, first released in 1991, is produced by Ipsen Ltd and is another botulinum toxin A. Like Botox, it is stored as a white lyophilized powder and requires reconstitution with saline prior to use. While it is not yet available in the United States, it is available in over 70 countries around the world. Dysport has been granted orphan drug status for the management of cervical dystonia by the FDA. In late 2007, Ipsen Ltd filed for a biologics license application. The FDA issued a Complete Response Letter in January 2009 that requested additional information, including the finalization of the Risk Evaluation and Mitigation Strategy (REMS) and of the draft labeling, as well as a Safety Update Report, but did not request any further studies (237). Ipsen reports optimism in bringing

the product to the US market. Numerous studies have been performed that have demonstrated safety and efficacy of the agent in spasticity of various etiologies (229–231,238–243). Currently, a large open-label trial of Dysport for the management of arm spasticity secondary to stroke is underway (244). Although Botox and Dysport are both botulinum toxin type A, they are not equivalent or interchangeable on a unit per unit dosage and the ratio between the two is 4 to 5/1 (195). As a result of a pilot study comparing three different doses of Dysport in the management of arm spasticity secondary to stroke (241), the recommended starting dosage for arm spasticity is 1,000 units.

**Botulinum Toxin B (Myobloc).** In December 2000, the FDA approved Elan Pharmaceutical's botulinum toxin type B product, under the trade name Myobloc for the indication of cervical dystonia. Therefore, like other botulinum toxins, using it for spasticity will be off label. Unlike Botox and Dysport, Myobloc does not require reconstitution and is packaged as a liquid preparation at a pH of 5.6 that can be used right out of the vial (245). The original abstract reports by BeDell et al. (246), Hecht et al. (247), Jayasooriya et al. (248) and Moberg-Wolff and Walke (249) suggested some efficacy for the treatment of spasticity and shoulder pain. However, the more recent literature concerning the use of the B toxins in the management of spasticity has been disappointing. A double-blind placebo-controlled trial by Brashear et al. (232) demonstrated numerous side effects while being unable to show significant improvement in upper limb spasticity. A higher dose may have achieved better clinical effects but would have risked greater side effects as well. Barnes et al. reported on their clinical work with the B toxin for patients who were A resistant. They reported that secondary to either nonefficacy or unacceptable side effects, only 13 of 36 patients with cervical dystonia and 7 of 20 patients with spasticity were continuing to be treated with the type B toxin (250). In another comparison study of Toxin A (Botox) versus Toxin B (Myobloc) in the management of cervical dystonia, the toxins were shown to have equivalent benefits at 4 weeks post injection. However, the A toxin demonstrated superiority with a longer duration of effect (14/12.1 weeks) and superior side effect profile. In regards to the side effect profile, there was a lower rate reported with the A toxin in regards to dysphagia (19%/48%) and dry mouth (41%/80%) (251).

### ***Side Effects***

Chemical denervation with botulinum toxin does lead to occasional side effects. Systemic absorption does occur and antibody formation is a real concern in the dystonia literature (252,253). Herrmann et al. (254) reported a rate of 31.8% antibody formation in serum samples of children who had received multiple injections of either Botox or Dysport for the management of spasticity. Yablon et al. published a study in 2007 examining antibody formation in patients treated with at least one session of botulinum toxin A (Botox) lot (BCB2024) for the management of post stroke spasticity. They found that

of the 191 patients sampled, only one (0.5%) demonstrated antibodies to botulinum toxin type A. They suggest that reduced risk of antibody formation may be due to the reduced protein load in the new batch of toxin (255).

Multiple studies have been published regarding the side effects of botulinum toxin injection. Reactions can be categorized as systemic or local and often depend on the area being treated. The most common systemic effects tend to be headache, flulike symptoms, fatigue, and nausea and are benign with no long-term sequelae (223). These have been reported after treatment of limb spasticity, oromandibular motor disorders, and urologic disorders (199,204,245,246). There are also case reports of iatrogenic botulism resulting in respiratory depression, dysphagia, generalized weakness, dysarthria, ptosis, and dry mouth in all treatment areas (199,203,204,257,258). Rare side effects also include a generalized skin exanthema following botulinum toxin type A injection and visual disturbances due to loss of accommodation secondary to parasympathetic dysfunction following Myobloc injection (255,259). The increased frequency of dry mouth and the reports of visual disturbances have led authors to the conclusion that Myobloc has more parasympathetic side effects than the type A toxins (245,260). The large multicenter studies of type A toxins also reported no increase in serious adverse events between placebo and treatment groups (212,216,221,256).

Local side effects tend to reflect the area injected. There may be pain and erythema at the injection site (196) and local diffusion to surrounding muscles can cause a variety of symptoms depending on the anatomic location. Treatment of limb spasticity may cause weakness in the surrounding muscles, while injections for cervical dystonia or bruxism have been reported to cause dysphagia, dysarthria, or difficulty swallowing (203,204,245).

Recently, the FDA issued an early warning for both types of botulinum toxin available in the United States in response to reports of serious systemic side effects. The side effects specified were suggestive of botulism and included patients experiencing difficulty holding up their heads, ptosis, dysphagia, respiratory insufficiency, weakness, numbness, as well as death. In the adult population, no deaths were reported, and none of the more severe side effects requiring hospitalization resulted in ventilatory support or a feeding tube. However, in the pediatric population, these measures were occasionally required, with some cases resulting in death. The doses used in the pediatric population ranged from 6.25 to 32 units/kg for Botox and 388 to 625 units/kg for Myobloc. In the adult population, Botox doses ranged from 100 to 700 units, while Myobloc doses varied from 10,000 to 20,000 units. This report is an early warning and further information will be obtained prior to a final determination by the FDA (261).

In summary, chemical denervation is a valuable treatment modality in the management of spasticity. Phenol and alcohol treatments require considerable skill to perform effectively, but clearly this method still has a place in the management of focal

spasticity. Botulinum toxin A has a long record of success in the treatment of spasticity. The B toxin is still relatively new, and its suitability in the spasticity treatment armamentarium is uncertain as there is no large-scale study demonstrating its safety and efficacy in spasticity management. The authors are unable to give a definitive answer at this time which toxin is more effective or antigenic than the other; however, there is substantially more supportive literature for the A toxin. There is no evidence to suggest that alternating agents delay antibody formation. Final answers will have to be deferred to sometime in the future. There also is no fixed ratio of conversion when switching toxins, as they are different but related drugs, in the same fashion as calcium channel blockers. At this time, the clinician's skill and judgment will be an important factor in the dosing decision.

## **Surgical Techniques**

### **Intrathecal Medications**

#### ***Baclofen***

One of the first reports on the efficacy of ITB was by Penn et al. (262), who reported its benefit in severe spasticity in patients with MS and SCI. The authors demonstrated that ITB was acutely beneficial, via a double-blinded placebo ITB injection over 3 days. They also were able to demonstrate a long-term treatment effect ranging from 10 to 32 months after pump insertion in an open-label follow-up study. In 1993, Albright et al. (263) demonstrated that ITB was also useful in the management of CP-related spasticity. It was approved by the US FDA for intrathecal therapy for management of severe spasticity of cerebral origin in 1996. ITB has been shown to be useful and well tolerated in the treatment of other neurologic populations, including those suffering from TBI (264), anoxia (265), and stroke-related spastic hemiplegia (266–270). Adequate management of spasticity from cerebral origin with ITB generally requires higher dosing compared to spasticity of spinal origin (271).

Potential candidates for ITB undergo screening for potential efficacy. Their spasticity is evaluated at baseline followed by an intrathecal bolus of 50 µg of baclofen via lumbar puncture. If there is a substantial improvement in spasticity, the screen is considered successful. If the initial trial does not demonstrate improvement, it is repeated with an escalation of the dose up to a maximum bolus of 100 µg. If any of the above trials proves successful, the patient is offered the ITB system, with the starting dose often set at twice the effective bolus dose per 24 hours. For example, if the patient responded to a 100-µg bolus, the ITB system is set to run at 200 µg per 24 hours. For persons who have spasticity and are ambulatory, there is sometimes a question if the tone reduction will result in decreased mobility. A simple reduction in tone that is considered a success in the normal trial may not address functional issues adequately. A trial using a continuous infusion of ITB may be more appropriate in those cases. In 2007, Bleyenheuft et al. reported on their use of an external pump connected to an intrathecal

catheter on seven ambulatory patients with spasticity and CP. The authors found that not only did spasticity decrease but they were also able to assess the patient's ability to ambulate while on ITB. They reported complications of a chemical meningitis and two CSF leaks but were positive about the overall procedure's safety and efficacy (272).

The advantage of the ITB system is that it delivers a continuous supply of baclofen through a catheter that is directly connected to the subarachnoid space. As a result, there is reduced spasticity at a dose that is substantially lower than that required via oral administration (72). Dralle et al. (273) reported that required dosing was roughly 1% of that needed for oral administration. As a result, the CNS side effects that are commonly seen with oral antispasticity agents are greatly reduced with ITB (274). The placement of an ITB device should not be taken lightly. The system requires a commitment to a surgical procedure and the insertion of a foreign object that will have to be replaced in 3 to 7 years, based on current technology.

The ITB system, while often a good therapy choice, can be associated with adverse effects. Problems with the ITB device itself may include high cost (275), infection risk (276), CSF leaks (277), pump dysfunction, and kinking or disconnection of the catheter tubing (278). Problems associated with the ITB medication administration may include baclofen overdose, withdrawal and associated seizures (279–281), and chronic constipation. Some studies reveal concern for another long-term adverse effect of ITB therapy of rapid progression of scoliosis (282–284).

Originally, the most cephalad placement of the catheter was between the levels of T8 and T10 (285). More recently, surgeons have been placing it higher (264,286) and reported significant improvement in spasticity in both the upper and lower extremities. Broseta et al. (287) reported the safe administration of ITB, with the catheter placed as high as C4. The reason for limiting the cephalad catheter placement is concern for respiratory suppression, with baclofen administration near muscles of respiration. ITB has proven beneficial for spastic hypertonia in patients with poststroke unilateral symptoms, without reducing weakening the unaffected limb (268).

### **Other Intrathecal Medications**

Baclofen is not the only medication that has been used intrathecally. Other pharmacologic agents that have been administered intrathecally, either alone or in combination with baclofen, include clonidine, midazolam, morphine, lidocaine, and fentanyl (288–292). Fentanyl has been shown to be effective in cases of developed resistance to ITB (290). Midazolam, a benzodiazepine, has been used intrathecally for the management of spasticity. Work in animals shows that the agent functions as a CNS depressant, analgesic, anticonvulsive, and myorelaxant (81). Some studies report neurotoxicity from intrathecal midazolam, with animal data showing potential toxicity to the blood-brain barrier, neurons, and the myelin sheath (293,294). As a result, its use in humans is controversial and has been

demonstrated in case reports for pain management (81,295–298). Finally, midazolam use for spasticity management is also limited by its sedating properties.

**Intrathecal Morphine.** Morphine has also been used intrathecally in the management of spasticity, with reduction in tone noted with boluses of 1 to 2 mg (299) and doses of 2 to 4 mg administered daily in the treatment of SCI-induced spasticity (300). The authors also reported that only one of the 12 patients who had responded to treatment had become resistant after 3 years of treatment. Intrathecal morphine has been used successfully in combination with ITB to control spasticity and pain in patients with MS (301). Case report evidence also supports using intrathecal morphine to control spasticity as a temporary agent for a “drug holiday” from ITB in cases of ITB resistance (302). The significant side effect profile of intrathecal morphine limits its use, including development of tolerance, itching, GI disturbances, hypotension, and urinary retention (81). Lydon et al. (303) reported problems with gastric emptying, whereas Glass (304) reported that an intrathecal bolus dose of 0.4 mg induced respiratory depression. Itching is the most common side effect with intrathecal morphine, whereas respiratory depression, common with doses of 1 to 2.5 mg, is the most troubling. As a result, the role of intrathecal morphine in the management of spasticity is uncertain (81).

**Intrathecal Clonidine.** Intrathecal clonidine has also been used in the management of spasticity (288), especially in spinal cord patients (289). Remy-Neris et al. (305) reported that the use of intrathecal clonidine on patients with incomplete SCI showed significant electrophysiologic changes, in addition to three of eight patients demonstrating improvements in gait velocity. It has also been shown to demonstrate decreases in the stretch reflex in this population. The functional results of intrathecal clonidine are mixed. In the previously mentioned trial, three participants did indeed demonstrate an increase in their preferred walking speed, and three others demonstrated a decrement in their performance (loss of their ability to stand), most likely as a result of the functional benefits of their tone. This loss of the ability to stand was not dose related (289). Another potential benefit of intrathecal clonidine is its ability to reduce detrusor hyperreflexia in the SCI population (306,307).

The side effect profile for intrathecal clonidine is potentially problematic. In addition to the functional loss reported earlier, intrathecal clonidine can also cause cardiac problems (hypotension, bradycardia, and decreased cardiac blood flow) (289,308), dry mouth, and sedation. In particular, the hemodynamic side effects of intrathecal clonidine may be its most limiting factor (81).

### **Other Neurosurgical Procedures**

In addition to intrathecal administration of pharmacologic agents, other neurosurgical procedures are available for the management of spasticity. DRR is a procedure that has

demonstrated efficacy in the management of spasticity. This procedure should be considered when the patient's condition has been recalcitrant to other more conservative measures or when financial or compliance issues direct treatment interventions. Much of the evidence demonstrating the efficacy of rhizotomy is found in the CP literature (309–312). DRR has been shown to be useful in other populations, such as those with MS (313,314). A radiofrequency rhizotomy was performed by Kasdon and Lathi in 1974, and the authors reported significant improvement in 24 of the 25 patients treated (315).

Initially, rhizotomy did not selectively ablate motor and sensory roots. The technique of interrupting a limited number of the most pathologic sensory rootlets and sparing the remainder was an innovation derived later in the history of the rhizotomy procedure. This method, called a selective DRR, reduces the propensity of anesthesia due to sensory nerve root ablations and leaves the motor system intact. Much work concerning this subject has been published by Sindou et al. (314,316,317). Studies have shown that the selective DRR continues to be beneficial years after surgery. Gul et al. (310) showed that 5 years after surgery, their patients still maintained improvements in tone and muscle strength. Mittal et al. (318) demonstrated that fine motor improvement seen after 1 year was still maintained at 3- and 5-year follow-up. Other more recent studies by Langerak et al. in 2007 and 2008 (319,320) demonstrated preservation of improved ROM in the lower extremities and ambulation 20 years after DRR, with none of the patients reporting the need for help with ADL. DRR has also been shown to reduce the need for orthopedic surgery, particularly soft-tissue procedures, which is best achieved when performing the DRR in younger patients with CP (321).

While the functional benefits of DRR appear to be maintained many years after the procedure, several studies have evaluated the long-term effects, particularly on the progression of spinal deformities. Steinbok (322) showed in a study of 104 children with spastic CP who underwent selective DRR that 54.8% had scoliosis greater than or equal to 10 degrees and six had a more significant scoliosis greater than 35 degrees. These numbers, however, were within the range of incidence of scoliosis in patients with spastic CP who did not undergo the surgical procedure, and only three of the patients required surgical intervention to correct the deformities. Nonetheless, the authors concluded that awareness of the progression of spinal deformities after selective DRR may be an important consequence to consider. Farmer and Sabbagh (323) studied 101 patients with a mean follow-up of approximately 6 years, showing that scoliosis was present in 45%, but only in two cases did the curve reach above 20 degrees, and no cases required bracing or fusion. Overall, Farmer and Sabbagh concluded that the natural history of spinal deformity in children with spastic CP was not worsened by selective DRR, and in fact the procedure before the age of 5 has a protective effect on lordosis.

Numerous complications have been reported as a result of selective dorsal root DRR, but they are often transient. Complications include bronchospasm, aspiration pneumonia,

urinary retention, ileus, sensory loss, hypotonia, and bowel dysfunction (324–326). Nonetheless, the authors of these studies concluded that the benefits of the procedure far outweigh the potential complications.

There has been some controversy regarding the number and selection of rootlets to be ablated. Mittal et al. (327) stated that using electrophysiologic stimulation to identify nerve rootlets was very effective in choosing pathologic rootlets for ablation. They also reported the rootlet scoring was 93% reproducible and felt their technique resulted in great reduction in tone with only very limited loss of strength. On the other hand, Sacco et al. (328) reported that they had similar results to selective DRR when they performed nonspecific DRR on ten patients. Finally, Bertelli et al. (329) reported a new method in the treatment of upper-extremity spasticity. They performed a brachial plexus DRR and reported reduction in tone without any sensory difficulties. In summary, selective DRR remains a possible treatment option for spasticity, particularly in patients with CP, but its benefits, long-term outcomes, and proper case assignment remain controversial (330).

For patients unable to benefit from any of the above interventions, other aggressive modalities such as myelotomy or cordotomy are available. These procedures are generally reserved for intractable cancer pain, and most studies describing myelotomy or cordotomy involve pain management (331–333). Bischoff has advocated the use of myelotomy or cordotomy in severely spastic patients; however, these more aggressive interventions are controversial because they may cause dysfunction of the bowel and bladder (72).

### Orthopedic Procedures

Although the preceding discussion highlights the numerous pharmacologic and therapeutic modalities available in the management of spasticity, sometimes orthopedic interventions are still necessary. Rhizotomy, oral agents, and intrathecal agents are unable to act directly on muscle and tendon, the way a chemoneurolytic or orthopedic procedure can. This may be especially true in the management of childhood-related spasticity (334), where orthopedic surgical intervention can be effective in improving both function and the limitation of complications.

Orthopedic procedures are often irreversible, and physicians sometimes experience resistance from patients and their family. As a consequence, realistic goal setting is critical and requires that the family, health care providers, and patients, all be in agreement. It is also important for the treatment team to understand the pathophysiology, kinesiology, and overall patient function. Improper preprocedure planning can result in limited benefit or even a worsening of the patient's function and quality of life. When planned, executed, and given appropriate follow-up, orthopedic interventions can improve positioning or hygiene and can play a major role in active functioning tasks such as ambulation (72).

In the limited space available here, it is impossible to discuss all surgical options. The goal is to assist the reader in developing general principles for management decisions.

As mentioned earlier, careful planning is critical before any operation. If available, dynamic EMG can be exceptionally beneficial in the decision-making process (72). This point was demonstrated effectively by a 2003 study performed by Keenan et al. The authors investigated the role of dynamic motor control studies on their planning of orthopedic intervention on 21 patients with spastic elbow deformity. Two orthopedic surgeons were asked to plan a surgical intervention before and after motor studies were performed. As a result of the evaluation, the surgical plans were changed 57% of the time after the dynamic testing was performed (335).

When this type of testing is not available, previous results from chemoneurolysis and temporary nerve blocks, in addition to clinical evaluation, may assist in the decision process. The evaluation should look for muscles co-contracting or firing out of phase. These muscles may benefit from lengthening or a transfer of distal attachment site.

An example is a brachioradialis muscle that fires during attempted extension. Transferring the muscle's distal insertion to the extensor surface will allow it to be of assistance rather than a hindrance. Another example is foot inversion during gait. This movement can be caused by a host of muscles, such as the gastrosoleus complex, tibialis anterior, tibialis posterior and flexor digitorum longus, and flexor and extensor hallucis longus. Dynamic EMG (336) or selective botulinum toxin injection may help identify the offending muscle or muscles.

Based on these tests and clinical evaluation, surgery can be planned and performed with the best chance for functional benefit. Increased activity involving elbow flexion may require the treatment of one, two, or all three elbow flexors that can be treated with lengthening procedures (337). When addressing the shoulder for spasticity, pain, or function, it is important to correctly identify and target specific muscles to optimize the intervention (335). The tibialis anterior is best known for its critical function related to ankle dorsiflexion. It can also, when overfiring, cause inversion of the foot during swing phase. The split anterior tibial tendon transfer procedure, which divides the tendon's distal attachment on the medial surface and anchors it into the medial and lateral aspect of the foot, reduces the inversion moment with limited loss of dorsiflexors strength (338). Both passive and sometimes functional improvement can be seen when hyperactivity and knee flexion contractures are treated with a release of the hamstrings with positional improvement (339). With shortening of the Achilles tendon, the performance of a Z-plasty procedure that lengthens the tendon may be of benefit. However, there may be some loss of strength at the ankle joint as a result. Keenan et al. (340) showed that transfer of the flexor hallucis and the digitorum longus to the os calcis improved ankle strength and reduced the need for long-term use of a brace. An iliopsoas tenotomy may be necessary when there is significant spasticity or a hip flexor contracture of greater than 20 degrees after the application of more conservative measures (339). In patients with severe spasticity from MS or CP, the problem of hip subluxation may be encountered. This can be treated with adductor myotomies, or if not successful, femoral osteotomy (72).

More aggressive intervention may be appropriate in more severely affected patients. A 2007 report on eight severely impaired, nonambulatory patients with hip and knee flexure contractures over 90 degrees, evaluated the results of knee disarticulation and hip flexor release. It demonstrated significantly improved positioning, hygiene, passive ROM at the hip, quality of life, and decreased pain. In addition, all patients improved to the point that they were able to use a wheelchair after surgery (341).

Patients with severe spasticity often receive multiple types of treatments. Orthopedic surgery is often contemplated in combination with, or instead of, ITB or DRR. Gerszten et al. (342) reviewed the CP literature. They found that 18 out of 28 patients who were to undergo orthopedic procedures after ITB placement did not require it, as their spasticity had substantially improved. Grabb and Doyle (334) generally agree with this recommendation for their ambulatory patients with spasticity and structural issues, as they perform ITB or DRR before orthopedic intervention. Their exception was the lower-level ambulator, where they feel the tone is a functional benefit to ambulation and they are more likely to perform soft-tissue release first. For the nonambulatory patient, they recommend ITB before orthopedic intervention. Additionally, a 2006 review concluded that selective DRR reduces the requirement for orthopedic surgery compared to historical controls and that when performed at a young age (2 to 4 years old), selective DRR reduces the need for future orthopedic intervention (321).

## CONCLUSION

Muscle overactivity resulting from the UMNS continues to be a problem that can negatively affect a person's recovery and function. New treatment modalities have been developed that have greatly increased the options available to the treatment team. It is important for the physician to work together with other clinicians, the patients, and their caregivers to develop a comprehensive treatment approach with realistic and meaningful goals. With the rapid development of new treatments, greater improvement for even a longer period of recovery is possible. Clinicians should think creatively when choosing their treatment interventions and working in partnership with their patients strive for greater functional recovery.

# Neurogenic Bladder and Bowel

Voiding dysfunctions are commonly encountered in patients who are referred for rehabilitation. These voiding problems may result from medications, cognitive changes, physical impairments, or neurologic etiologies. Timely identification of voiding dysfunctions, treatment, and follow-up are important. This is particularly true in the rehabilitation setting, where voiding dysfunctions may cause patient embarrassment, interruption of therapy, and increased morbidity and ultimately may make the difference between reintegration into the community and being confined to a home or nursing home.

## ANATOMY AND PHYSIOLOGY OF THE UPPER AND LOWER URINARY TRACTS

### Upper Urinary Tracts

The kidney is composed of two parts: the renal parenchyma, which secretes, concentrates, and excretes urine; and the collecting system, which drains urine from multiple renal calyces into a renal pelvis. The renal pelvis then narrows to become the ureter. The point at which the renal pelvis becomes the ureter is known as the ureteropelvic junction (1).

The ureter travels down to the bladder. It is approximately 30 cm in length in the adult. The ureter has three areas of physiologic narrowing that take on clinical significance with respect to possible obstruction from stones. These areas are the ureteropelvic junction, the crossing over of the iliac artery, and the ureterovesical junction (2,3). The ureterovesical junction is the place where the ureteral orifice opens up into the bladder. Its function is to allow urine to flow into the bladder but prevent reflux into the ureter. This can be accomplished because the ureters traverse obliquely between the muscular and submucosal layers of the bladder wall for a distance of 1 to 2 cm before opening into the bladder (Fig. 51-1). Any increase in intravesical pressure simultaneously compresses the submucosal ureter and effectively creates a one-way valve (4). Presence of ureteral muscle in the submucosal segment also has been shown to be important in preventing reflux (5). However, if there is high intravesical pressure the submucosal segment can be compressed and prevent urine from draining down into the bladder, causing a physiological obstruction.

### Normal Urine Transport from the Kidneys to the Bladder

Urine transport is the result of both passive and active forces. Passive forces are created by the filtration pressure of the kidneys. The normal proximal tubular pressure is 14 mm Hg, and the renal pelvis pressure is 6.5 mm Hg, which slightly exceeds resting ureteral and bladder pressures. Active forces are the result of peristalsis of the calyces, renal pelvis, and ureter. Peristalsis begins with the electrical activity of pacemaker cells at the proximal portion of the urinary collecting tract (6).

For the ureter to propel the bolus of urine efficiently, the contraction wave must completely coapt the ureteral walls (7). Ureteral dilation for any reason results in inefficient propulsion of the urine bolus, and this can delay drainage proximal to that point. This can result in further dilation and, over time, lead to hydronephrosis.

### Lower Urinary Tracts

Anatomically, the bladder is divided into the detrusor and the trigone. The detrusor is composed of smooth muscle bundles that freely crisscross and interlace with each other. Near the bladder neck, the muscle fibers assume three distinct layers. The circular arrangement of the smooth muscles at the bladder neck allows them to act as a functional sphincter. The trigone is located at the inferior base of the bladder. It extends from the ureteral orifices to the bladder neck. The deep trigone is continuous with the detrusor smooth muscle; the superficial trigone is an extension of the ureteral musculature (see Fig. 51-1) (4).

There is no clear demarcation of the musculature of the bladder neck and the beginning of the urethra in a man or woman. In a woman, the urethra contains an inner longitudinal and outer semicircular layer of smooth muscle. The circular muscle layer exerts a sphincteric effect along the entire length of the urethra, which is approximately 4 cm long.

In a man, the urethra runs the length of the penis. It begins at the meatus and is surrounded by the spongy tissue of the corpora cavernosus. In addition to the corpora cavernosus, which runs on the underside of the penis, the penis is made up of two corpora cavernosa that contain the spongy erectile tissue. The urethra is divided into the posterior or prostatic urethra, extending from the bladder neck to the urogenital diaphragm, and the anterior urethra, which extends to the meatus. The junction between the anterior and posterior urethra is known as the membranous urethra.

**FIGURE 51-1.** Anatomy of the bladder and related structures in a woman. Note how the ureter tunnels for a distance through the bladder wall, helping to prevent vesicoureteral reflux. Also note that there is not a clear demarcation between the bladder neck and sphincter mechanism. (From Hinman F Jr. Bladder repair. In: Hinman F Jr, ed. *Urological Surgery*. Philadelphia, PA: WB Saunders; 1989:433.)

### Urinary Urethral Sphincters

Traditionally, the urethra has been thought to have two distinct sphincters, the internal and the external or rhabdosphincter. The internal sphincter is not a true anatomic sphincter. Instead, in both men and women, the term refers to the junction of the bladder neck and proximal urethra, formed from the circular arrangement of connective tissue and smooth muscle fibers that extend from the bladder. This area is considered a functional sphincter because there is a progressive increase in tone with bladder filling so that the urethral pressure is greater than the intravesical

pressure. These smooth muscle fibers also extend submucosally down the urethra and lie above the external rhabdosphincter (8).

In a man, the external or urethral rhabdosphincter often is diagrammatically illustrated as a thin circular band of striated muscle forming a diaphragm just distal to the prostatic urethra (i.e., membranous urethra). In an anatomic study, however, Myers et al. (8) reconfirmed earlier studies showing that the urethral external striated sphincter does not form a circular band but has fibers that run up to the base of the bladder. The bulk of fibers are found at the membranous urethra (9). This sphincter

is under voluntary control. The striated muscular fibers in both man and woman are thought to have a significant proportion of slow-twitch fibers with the capacity for steady tonic compression of the urethra. In a woman, striated skeletal muscle fibers circle the upper two thirds of the urethra (9).

## STRUCTURE AND FUNCTION OF THE MALE AND FEMALE CONTINENCE MECHANISM

In a man, the structures responsible for continence at the level of the membranous urethra include the mucosa, longitudinal smooth muscle of the urethra, striated sphincter, and levator ani musculature. Traditionally, the striated sphincter has been considered responsible for maintaining continence. However, experimental paralysis of the striated sphincter and levator ani following surgery for prostate outlet obstruction did not result in incontinence. This demonstrated the important role of the smooth muscle fibroelastic component of the membranous urethra. The increased tone at the bladder outlet (i.e., internal sphincter) also helps maintain continence (10).

In a woman, there are three important factors in maintaining continence:

Adequate pelvic floor support from the endopelvic fascia and anterior vagina.

Good sphincter function.

Maintenance of the intra-abdominal position of the proximal urethra.

During an increase in intra-abdominal pressure, continence is maintained by the downward-moving pelvic viscera compressing the urethra against the layer of endopelvic fascia and distribution of the increase of intra-abdominal pressure to the proximal intra-abdominal urethra. The urethral epithelium, which is sensitive to estrogen, is believed to help maintain continence by forming a mucosal seal (9).

## NEUROANATOMY OF THE LOWER URINARY TRACT

Urine storage and emptying is a function of interactions among the peripheral parasympathetic, sympathetic, and somatic innervation of the lower urinary tract. Additionally, there is modulation from the central nervous system (CNS).

### Bladder Neuroanatomy Efferent System

The parasympathetic efferent supply originates from a distinct detrusor nucleus located in the intermediolateral gray matter of the sacral cord at S2 to S4. Sacral efferents emerge as preganglionic fibers in the ventral roots and travel through the pelvic nerves to ganglia immediately adjacent to or within the detrusor muscle to provide excitatory input to the bladder. After impulses arrive at the parasympathetic ganglia, they travel through short postganglionics to the smooth muscle cholinergic receptors. These receptors, called cholinergic because the primary postganglionic neurotransmitter is acetylcholine, are distributed through the bladder. Stimulation causes a bladder contraction (11,12).

The sympathetic efferent nerve supply to the bladder and urethra begins in the intermediolateral gray column from T11 through L2 and provides inhibitory input to the bladder. Sympathetic impulses travel a relatively short distance to the lumbar sympathetic paravertebral ganglia. From here, the sympathetic impulses travel along long postganglionic nerves in the hypogastric nerves to synapse at  $\alpha$ - and  $\beta$ -adrenergic receptors within the bladder and urethra. Variations in this anatomic arrangement do occur; sympathetic ganglia sometimes also are located near the bladder, and sympathetic efferent fibers may travel along the pelvic as well as the hypogastric nerves (Fig. 51-2) (11,12).

Sympathetic stimulation facilitates bladder storage because of the strategic location of the adrenergic receptors.

**FIGURE 51-2.** Peripheral innervation of the bladder and urethra. Sympathetic stimulation responsible for storage travels through the hypogastric plexus. Parasympathetic stimulation causing bladder contractions travels through the pelvic nerve. (From Blaivas JG. Management of bladder dysfunction in multiple sclerosis. *Neurology*. 1980;30:73.)

**FIGURE 51-3.** Location of bladder receptors. Bladder storage is maintained by simultaneous sympathetic  $\alpha$ -adrenergic receptor (contraction) (A) and  $\beta$ -adrenergic receptor (relaxation) stimulation (B). Bladder emptying occurs with parasympathetic cholinergic receptor stimulation (C).

Beta-adrenergic receptors predominate in the superior portion (i.e., body) of the bladder. Stimulation of  $\beta$ -receptors causes smooth muscle relaxation. Alpha receptors have a higher density near the base of the bladder and prostatic urethra; stimulation of these receptors causes smooth muscle contractions and therefore increases the outlet resistance of the bladder and prostatic urethra (Fig. 51-3) (11–13).

After spinal cord injury (SCI), several changes occur to the bladder receptors that alter bladder function. There is evidence that when smooth muscle is denervated, its sensitivity to a given amount of neurotransmitter increases (i.e., denervation supersensitivity). Therefore, smaller doses of various pharmacologic agents would be expected to have a much more pronounced effect in those with SCI as compared with those with nonneurogenic bladders (14).

A change in receptor location and density may also occur. Norlen et al. (15) found that after complete denervation there was a change from a  $\beta$ -receptor predominance to an  $\alpha$ -receptor predominance. Because  $\alpha$ -receptors cause contraction of smooth muscle, a change in receptors may be one reason for some individuals to have poor compliance of the bladder after SCI.

Animal studies have revealed that, although the previously described long postganglionic neurons exist, there are ganglia close to the bladder and urethra in which there are both cholinergic and adrenergic fibers. This has been termed the *uro-genital short neuron system*. These ganglia are composed of three cell types, adrenergic neurons, cholinergic neurons, and small intensely fluorescent cells, which are believed to be responsible for this interganglionic modulation of the adrenergic and cholinergic neurons. Further work is needed to define this system in humans (16).

### Afferent System

The bladder afferent system transmits the mechanoreceptive input that is essential for voiding. The most important

afferents that stimulate voiding are those that pass to the sacral cord via the pelvic nerves. These afferents include two types of afferents, small myelinated A-delta and unmyelinated (C) fibers.

The small myelinated A-delta fibers respond in a graded fashion to bladder distention and are needed for normal voiding. The unmyelinated (C) fibers have been termed *silent C-fibers* because they do not respond to bladder distention and therefore are not essential for normal voiding. However, these silent C-fibers do exhibit spontaneous firing when they are activated by chemical or cold temperature irritation at the bladder wall. Additionally, the unmyelinated (C) fibers (rather than A-delta afferents) have been found to “wake up” and respond to distention and play an important role in stimulating uninhibited bladder contractions in following suprasacral SCI.

This role of the unmyelinated (C) fibers has been demonstrated in studies using intravesical administration of capsaicin and resiniferatoxin. Both of these agents are potent C-fiber afferent neurotoxins. In non-SCI animals (with A-delta afferents), there was no blockage of bladder contractions with bladder distention. However, in SCI animals (with “awake” C-fiber afferents), capsaicin completely blocked rhythmic bladder contractions induced with bladder distention (16). While intravesical capsaicin and resiniferatoxin are considered investigational drugs, similar results have been found in human studies in those with suprasacral SCI and multiple sclerosis (17). These findings have important potential therapeutic implications. However, further work is needed to determine the optimal dosage and vehicle for intravesical instillation (see Section “Management of Voiding Dysfunctions” later in this chapter).

### Bladder Neurotransmitters

It is known that there are more transmitters than acetylcholine and norepinephrine, including nitric oxide, vasoactive intestinal polypeptide, endogenous opioid peptides, and neuropeptide Y.

These transmitters may work independently or help modulate the classic neurotransmitters. Nitric oxide and vasoactive intestinal polypeptide have smooth muscle relaxant effects. This helps explain the concept of atropine resistance. It has been found that a single neurotransmitter-blocking agent such as atropine fails to suppress 100% of the bladder or urethral activity (14,18). This explains why a combination of agents may be more effective than a higher dose of a single agent.

### Urethral Sphincter Innervation

The external urethral sphincter classically has been described as having somatic innervation, allowing the sphincter to be closed at will. Somatic efferents originate from a pudendal nucleus of sacral segments from S1 to S4. Somatic efferents then travel through the pudendal nerve to the neuromuscular junction of the striated muscle fibers in the external urethral sphincter.

The internal urethral sphincter has been described as being under control of the autonomic system. This area has a large number of sympathetic  $\alpha$ -receptors, which cause closure when stimulated. Animal studies have revealed that nitric oxide is an important parasympathetic neurotransmitter mediating relaxation of the urethral smooth muscle (8,18).

The distinction between the internal and external sphincter is becoming less clear. Elbadawi and Schenk (19) reported histochemical evidence of a triple innervation pattern of the external sphincter (i.e., rhabdosphincter) in five mammalian species, with dual sympathetic and parasympathetic autonomic components superimposed on the somatic component. Sundin and Dahlstrom (20) demonstrated sprouting and increasing adrenergic terminals after parasympathetic denervation in cats. Crowe et al. (21) reported a substantial invasion of adrenergic nerve fibers in smooth and striated muscle in the urethra in SCI patients with lower motor neuron lesions.

### Influences of the Central Nervous System on the Lower Urinary Tract

Facilitation and inhibition of the autonomic nervous system are under control of the CNS. There are several theories of how this occurs. Denny-Brown and Robertson (22) suggested that micturition was primarily mediated by a sacral micturition reflex. According to their theory, descending nervous system pathways modulate this micturition reflex (21). Barrington, Bradley, and de Groat thought that facilitative impulses to the bladder originated from a region of the anterior pons termed “Barrington’s center” (23).

De Groat and associates additionally stressed the importance of the sympathetic nervous system in facilitating urine storage (24). Carlsson provided evidence that this pontine mesencephalic area also plays a role in coordinating detrusor and sphincter activity. Stimulation of Barrington’s center significantly decreased electromyographic (EMG) activity in the periurethral-striated sphincter while causing a bladder contraction (25).

Transection experiments in cats suggest that the net effect of the cerebral cortex on micturition is inhibitory. This also is

true for the basal ganglia and corresponds to clinical findings of detrusor hyperreflexia in those with basal ganglia dysfunction (e.g., Parkinson’s disease). The cerebellum is thought to maintain tone in the pelvis floor musculature and influence coordination between periurethral striated muscle relaxation and bladder emptying (15,25).

### Normal Voiding Physiology

Micturition should be considered as having two phases: the filling (storage) phase and the emptying (voiding) phase. The filling phase occurs when a person is not trying to void. The emptying phase occurs when a person is attempting to void or told to void.

During filling (filling or storage phase), there should be very little rise in bladder pressure. As filling continues, low intravesical pressure is maintained by a progressive increase in sympathetic stimulation of the  $\beta$ -receptors located in the body of the bladder that cause relaxation, and stimulation of the  $\alpha$ -receptors located at the base of the bladder and urethra that cause contraction. Sympathetic stimulation also inhibits excitatory parasympathetic ganglionic transmission, which helps suppress bladder contractions. During the filling phase, there is a progressive increase in urethral sphincter EMG activity (26). Increased urethral sphincter activity also reflexly inhibits bladder contractions. When a bladder is full and has normal compliance, intravesical pressures are between 0 and 6 cm H<sub>2</sub>O and should not rise above 15 cm H<sub>2</sub>O. Filling continued past the limit of the viscoelastic properties of the bladder results in a steady progressive rise in intravesical pressure (27). This part of the filling curve usually is not seen in a person with normal bladder function, because this much distension would cause significant discomfort and not be tolerated.

When a patient is told to void (voiding or emptying phase), there should be cessation of urethral sphincter EMG activity as well as a drop in urethral sphincter pressure and funneling of the bladder neck. There is no longer reflex inhibition to the sacral micturition center from the sphincter mechanism. This is followed by a detrusor contraction. The urethral sphincter should remain open throughout voiding, and there should be no rises in intra-abdominal pressure during voiding. In younger individuals, there should be no postvoid residual, although postvoid residuals may increase with aging.

### Geriatric Voiding Physiology

The aging process often affects voiding physiology. The kidneys undergo an age-related decrease in glomerular blood flow and renal blood flow (28). The elderly also experience a loss in concentrating ability and often excrete most of their fluid intake at night, even in the absence of medical conditions such as prostate outlet obstruction, diabetes, remobilization of lower-extremity edema, and use of evening diuretics (29).

Detrusor overactivity has been reported as the most common type of voiding dysfunction in incontinent elderly men and women (29). More recently, this has been called an *overactive bladder*. This may be associated with a central nervous lesion (such as a stroke, head injury, cervical disk disease, etc.).

A replacement of normal muscle cell junctions by novel “protrusion junction cells” and ultraclose abutments, connecting cells into chains, which facilitates and increases spontaneous smooth muscle activity, has been found in incontinent elderly patients (30). There is often a combination of causes that result in an overactive bladder. Detrusor hyperactivity may coexist with impaired contractility (DHIC) of the bladder wall, resulting in both incontinence and retention. This combination was found to be one of the most common urodynamic findings in the elderly incontinent nursing home population (29). A combined pattern may also occur if there are cognitive/mobility issues and a person begins to void (incontinence) and then stops voiding.

Outlet obstruction by prostatic hypertrophy is the second most common cause of incontinence in men, although most men with outlet obstruction do not have incontinence (29). Outlet obstruction results in a significant increase in collagen, leading to bladder trabeculation. This in turn can cause a decrease in the viscoelastic properties for storage as well as the ability to contract and may be one reason for increasing postvoid residuals and decreasing bladder capacity with aging (31). It should be noted that outlet obstruction in women is rare; however, it may occur from various etiologies, such as urethral stenosis or kinking from a large cystocele or a previous bladder neck suspension. A trabeculated bladder appearance in older women without obstruction usually results from a thinning of the bladder wall with more prominent muscle bundles rather than deposition of collagen (31).

Stress incontinence is the second most common cause of incontinence in elderly women (29). In younger women, stress incontinence frequently results from pelvic laxity; however, in elderly women, it is also caused by a decrease in urethral closure pressure. This decrease in urethral pressure has been attributed to a decrease in estrogen, which causes a loss of muscle bulk and atrophic changes of the urethra and vagina. This, in turn, can cause inflammation and friability of these tissues, decreased periurethral blood flow, further laxity of pelvic structures, and possible urethral prolapse (31).

Detrusor underactivity may also occur with aging. At a cellular level, this has been characterized by widespread degenerative changes of both muscle cells and axons without accompanying regenerative changes (32). Ouslander et al. (33) reported that approximately 25% of elderly patients evaluated had postvoid residuals greater than 100 mL. Approximately 10% of geriatric incontinence has been attributed to overflow incontinence (29).

### Pediatric Voiding Physiology

Voiding physiology also changes with age in children. In the newborn, the sacral micturition reflex is primarily responsible for voiding. Because the brain stem is intact, there is coordination of the bladder contraction with sphincter relaxation; however, there is little inhibition of the micturition reflex from the cerebral cortex. As the child grows, the voided volume increases and voiding frequency decreases. By 3 years of age, most children have some voluntary control of voiding. This control usually is complete by the age of 4 years. There

are some neurologically intact children, however, for whom complete control of voiding may take 5 or 6 years (34).

## CLASSIFICATION OF VOIDING DYSFUNCTION

There have been a wide variety of classifications to describe voiding dysfunctions. These classifications have been based on neurologic lesion (e.g., Bors-Comarr, Bradley), urodynamic findings (e.g., Lapedes), functional classification (e.g., Wein), and combination of bladder and urethral function based on urodynamics (e.g., International Continence Society) (35–39). The International Continence Society classification: The Standardisation of Terminology of Lower Urinary Tract Function: Report from the Standardisation Sub-committee of the International Continence Society has become widely accepted not only because it provides a standardization of terminology describing bladder and urethral function but also because a description of each of these terms is provided (39). Table 51-1 shows some highlights of

**TABLE 51.1** Urodynamic Terminology—  
Highlights From International  
Continence Society Classification

Bladder
Bladder—function
Normal (during filling)
Detrusor overactivity (during filling)
Neuropathic detrusor overactivity
Idiopathic detrusor overactivity
Normal (during emptying)
Underactive (during emptying)—inadequate magnitude or duration of a contraction to empty the bladder
Acontractile (no contractions during urodynamics)
Areflexic (no contractions due to neurogenic cause)
Bladder—sensation
Normal
Increased
Reduced
Absent
Nonspecific
Bladder capacity
Small (350 mL)
Average (350–650 mL)
Large (650 mL)
Compliance
Low (hypocompliance)
Normal (350–650 mL with little pressure rise)
High (hypercompliance)
Urethra
Normal
Incompetent (during filling)
Obstructive (during voiding)
Mechanical (stricture, bladder outlet obstruction)
Overactive (detrusor/[external] sphincter dyssynergia)

TABLE 51.2	Urodynamic and Functional Classification
Incontinence	
Caused by the bladder	
Detrusor overactivity	
Decreased capacity	
Low bladder wall compliance	
Normal (cognitive/mobility issue)	
Caused by the outlet	
Incompetent sphincter	
Retention	
Caused by the bladder	
Detrusor areflexia	
Large capacity/high compliance	
Normal (cognitive/mobility issue)	
Caused by the outlet	
High voiding pressure with low flow rate	
Internal sphincter dyssynergia	
External sphincter dyssynergia	
Overactive sphincter mechanism (i.e., sphincter or pseudosphincter dyssynergia)	
Retention and incontinence	
Caused by the bladder	
Uninhibited contractions with underactive detrusor	
No contractions	
Normal (cognitive/mobility issue)	

the urodynamic terminology from International Continence Society Classification. Table 51-2 shows Wein’s classification. This classification is helpful at directing treatment because it is based on a clinical problem (incontinence or retention), which can then be applied to specific urodynamic findings. A urodynamic basic SCI data set has recently been developed, which should be helpful, collecting information in a standardized way regarding urodynamic bladder and sphincter function in those with SCI (40).

VOIDING DYSFUNCTIONS FOUND IN COMMON NEUROLOGIC DISORDERS

Suprapontine Lesions

Any suprapontine lesion may affect voiding. Lesions may result from cerebrovascular disease, hydrocephalus, intracranial neoplasms, traumatic head injury, Parkinson’s disease, and multiple sclerosis. It should be noted that multiple sclerosis is unique among the suprapontine lesions because it also affects the white matter of the spinal cord and often has a relapsing and remitting nature. The expected urodynamic finding following a suprapontine lesion is detrusor hyperreflexia without detrusor-sphincter dyssynergia. Because of various factors such as medications, prostate obstruction, and possible normal bladder function but poor cognition, the voiding dysfunctions may be very different from expectations. Voiding dysfunction

following cerebrovascular accident (CVA), Parkinson’s disease, and multiple sclerosis has been studied more extensively than those associated with other suprapontine lesions and is reviewed in the following discussion.

Cerebrovascular Accidents

After a CVA, some patients initially have acute urinary retention. The reason for this detrusor areflexia is unknown. Urinary incontinence, however, is the most common urologic problem following an acute CVA. Various series have reported that 40% to 60% of patients are incontinent 1 week post-CVA (41–43). In the inpatient rehabilitation setting, a 33% incidence of incontinence during the first 3 months post-CVA has been reported (44). It also has been well documented that this problem significantly improves or resolves in the majority of patients. At 1 month, the percentage of incontinent patients dropped to between 29% and 42%. By 6 months to 1 year post-CVA, 14% to 15% of patients still were incontinent, which is similar to the 15% to 30% incidence in the general geriatric population (41–43). Risks for incontinence poststroke include age greater than 75 years, dysphagia, motor weakness, and visual field defects. At 2 years poststroke, incontinent patients versus continent patients had higher case fatality rates (67% vs. 20%), higher institutional rates (39% vs. 16%), and grater disability (39% vs. 5%) (43). A recent study has further categorized poststroke urinary incontinence as urge incontinence or impaired awareness urge incontinence. Those with impaired awareness urge incontinence had poorer attention and outcomes. Impaired awareness incontinence was also found to be a strong predictor factor for mortality and nursing home residence at 1 year. It would be expected that those with impaired awareness incontinence would not do well (45).

Detrusor overactivity with uninhibited bladder contractions is the most common urodynamic finding following a stroke. It has been reported to occur 70% to 90% of the time (42,46). One hypothesis for this finding is the release of the spinal micturition reflexes from the inhibitory higher centers. Symptoms, however, often do not correlate with urodynamic findings. Linsenmeyer and Zorowitz evaluated 33 consecutive incontinent patients who were 1 to 3 months post-CVA. They found that whereas 82% of men had uninhibited contractions, 43% also had urodynamic evidence of outlet obstruction. Six percent of the incontinent group had no bladder contractions and twelve percent had normal urodynamic findings (46). Voluntary sphincter contractions (i.e., pseudodyssynergia) to keep from voiding should not be misinterpreted as true detrusor-sphincter dyssynergia. In a review of 550 patients, Blaivas (47) reported that patients with CVAs do not develop true detrusor-sphincter dyssynergia. EMG studies by Siroky and Krane (48) gave similar results.

Parkinson’s Disease

Symptoms of bladder dysfunction have been reported in 37% to 72% of patients with Parkinson’s disease. These symptoms may be frequency or urgency (57%), obstruction (23%), or a combination of the two (20%). Detrusor overactivity has

been the most common urodynamic finding (72% to 100%) (49–51). Detrusor overactivity is thought to occur because of loss of the inhibitory input from the basal ganglia on the micturition reflexes; however, detrusor instability also has been associated with benign prostatic obstruction. Detrusor areflexia may result from bladder decompensation through a combination of bladder outlet obstruction and chronic use of anticholinergic and  $\alpha$ -adrenergic medications (51).

EMG studies of the external sphincter reveal that patients may have pseudodyssynergia or bradykinesia but not true detrusor-sphincter dyssynergia (49–51). The majority of patients (63% to 75%) have normal sphincter function (49–51).

### Multiple Sclerosis

Only 6% of patients with multiple sclerosis first present with urologic symptoms (52). Bemelmans and associates, however, reported that 50% of asymptomatic patients with early multiple sclerosis had urodynamic abnormalities that needed further follow-up, and 50% of these required therapeutic intervention (53). As the disease progresses, urologic symptoms become common, eventually affecting at least 50% of men and 80% of women (54). The type of voiding dysfunction often is difficult to predict because of the diffuse involvement and changing nature of the disease.

Goldstein et al. reported that in a series of 86 symptomatic patients, 49% had incontinence, 32% had urgency and frequency, and 19% had obstructive hesitancy and retention. They also documented that patients with similar neurologic findings may have different voiding dysfunctions and that urologic signs and symptoms do not accurately reflect the voiding dysfunction (55). Wheeler et al. found that 55% of patients who were studied had changes in their urodynamic picture. The urodynamic pattern varied from detrusor areflexia to detrusor overactivity and vice versa (56).

Because suprapontine and suprasacral plaques occur most frequently, detrusor hyperreflexia is the most common urodynamic finding; however, as many as 50% of patients have poorly sustained uninhibited bladder contractions with inefficient bladder emptying. Detrusor areflexia is found in approximately 20% of patients with urologic symptoms. This is believed to be a result of sacral plaque involvement (57).

True detrusor-sphincter dyssynergia may occur in multiple sclerosis when there is involvement of the suprasacral spinal cord. Approximately 15% to 20% of patients develop detrusor-sphincter dyssynergia. Blaivas and Barbalias (58) reported that this was an ominous sign because of the potential for upper-tract damage and development of reflux as a result of the increased intravesical pressures needed to force urine past the dyssynergic sphincter. Upper-tract pathologic processes, including pyelonephritis, renal calculi, reflux, and hydronephrosis, have been reported to occur in 10% to 20% of patients with multiple sclerosis (58,59).

### Suprasacral Spinal Cord Lesions

Traumatic SCI is the most common suprasacral lesion affecting voiding. Other suprasacral lesions include transverse

myelitis, multiple sclerosis, and primary or metastatic spinal cord tumor.

Patients with suprasacral spinal cord lesions would be expected to have detrusor hyperreflexia with detrusor-sphincter dyssynergia. However, in cases of partial lesions, occult lesions of the sacral cord, or persistent spinal shock, this is not always the case (60).

Traumatic suprasacral SCI results in an initial period of spinal shock, in which there is hyporeflexia of the somatic system below the level of injury and detrusor areflexia. During this phase, the bladder has no contractions, even with various maneuvers such as water filling, bethanechol supersensitivity testing, or suprapubic tapping. The neurophysiology of spinal shock and its recovery are not known. Recovery of bladder function usually follows recovery of skeletal muscle reflexes. Uninhibited bladder contractions gradually return after 6 to 8 weeks (61).

Clinically, a person with a traumatic suprasacral SCI may begin having episodes of urinary incontinence and various visceral sensations, such as tingling, flushing, increased lower-extremity spasms, or autonomic dysreflexia with the onset of uninhibited contractions. As uninhibited bladder contractions become stronger, the postvoid residuals decrease. Rudy et al. (62) reported that voiding function appears optimal at 12 weeks postinjury. However, detrusor hyperreflexia has been reported to have a delayed onset of up to 22 months postinjury. Eventually, all of these patients did develop uninhibited contractions (63). Bors and Comarr (35) considered the bladder “balanced” when postvoid residuals were less than 20% of the total bladder capacity in those with detrusor hyperreflexia. Graham (64) reports that 50% to 70% of patients will develop balanced bladders without therapy. Unfortunately, high intravesical voiding pressures usually are required for the development of a balanced bladder. These high pressures may cause renal deterioration.

Traditionally, it has been thought that there is decreased activity of the external urethral sphincter during acute spinal shock. However, Downie and Awad (65) noted in dogs that with surgical transection between T2 and T8, there was no change in the activity of the periurethral striated musculature despite detrusor areflexia. In humans, Nanninga and Meyer (66) found that in 44 patients in spinal shock with suprasacral lesions, all had a positive bulbocavernosus reflex, and 30 of 32 had sphincter activity despite detrusor areflexia within 72 hours of injury. Koyanagi et al. noted that external sphincter electrical activity was not affected during acute spinal shock but was likely to increase after recovery from spinal shock. This increase was more marked in those with high suprasacral lesions than in those with low suprasacral lesions (67).

Detrusor–external sphincter dyssynergia often occurs following suprasacral lesions. Blaivas et al. (68) noted that it occurred in 96% of patients with suprasacral lesions. They found several different patterns of striated sphincter dyssynergia. Rudy et al. proposed that detrusor-sphincter dyssynergia is an exaggerated continence reflex. The continence reflex is the normal phenomenon of increasing urethral sphincter

activity with bladder filling. They believed that the patterns described by Blaivas et al. (62) represented variations of the single continence reflex.

In addition to the detrusor–external sphincter dyssynergia, internal sphincter dyssynergia also has been reported, often occurring at the same time as detrusor–external sphincter dyssynergia.

### Sacral Lesions

There are a variety of lesions that may affect the sacral cord or roots. These include spinal trauma, herniated lumbar disk, primary or metastatic tumors, myelodysplasia, arteriovenous malformation, lumbar stenosis, and inflammatory process (e.g., arachnoiditis). In Pavlakis et al. series, trauma was responsible for conus and cauda equina lesions more than 50% of the time. The next most common cause was L4/L5 or L5/S1 intervertebral disc protrusion. The incidence of lumbar disc prolapse causing cauda equina syndrome is between 1% and 15% (69). Damage to the sacral cord or roots generally results in a highly compliant acontractile bladder; however, particularly in patients with partial injuries, the areflexia may be accompanied by decreased bladder compliance, resulting in progressive increases in intravesical pressure with filling (70). The exact mechanism by which sacral parasympathetic decentralization of the bladder causes decreased compliance is unknown (70,71).

It has been noted that the external sphincter is not affected to the same extent as the detrusor. This is because the pelvic nerve innervation to the bladder usually arises one segment higher than the pudendal nerve innervation to the sphincter (72). The nuclei also are located in different portions of the sacral cord, with the detrusor nuclei located in the intermediolateral cell column and the pudendal nuclei located in the ventral gray matter. This combination of detrusor areflexia and an intact sphincter helps contribute to bladder overdistention and decompensation.

### Peripheral Lesions

There are multiple etiologies for peripheral lesions that could affect voiding. The most common lesion is a peripheral neuropathy secondary to diabetes mellitus. Other peripheral neuropathies that have been associated with voiding dysfunction include chronic alcoholism, herpes zoster, Guillain-Barré syndrome, and pelvic surgery (73,74). A sensory neuropathy is the most frequent finding in diabetes. Urodynamic findings, including decreased bladder sensation, chronic bladder overdistention, increased postvoid residuals, and possible bladder decompensation, may result from bladder overdistention secondary to decreased sensation of fullness. Andersen and Bradley (75) reported that in their series, mean bladder capacity was 635 mL, with a range of 200 to 1,150 mL. An autonomic neuropathy also may be responsible for decreased bladder contractility. Guillain-Barré syndrome and herpes zoster are predominantly motor neuropathies. Transient voiding symptoms, predominantly urinary retention, have been reported to occur in 0% to 40% of patients and are thought to represent

involvement of the autonomic sacral parasympathetic nerves. Detrusor hyperreflexia occasionally has been found in those with Guillain-Barré syndrome (76). Voiding dysfunctions resulting from pelvic surgery or pelvic trauma usually involve both motor and sensory innervation of the bladder (75).

## COMPREHENSIVE EVALUATION OF VOIDING DYSFUNCTION

### Neurolgic History

The urological history should first focus on the patient's voiding symptoms. The history should establish whether the onset of the current symptoms is new, has become worse, or has remained unchanged since the neurologic insult. This will allow for more meaningful discussions when patients and family ask about "returning to normal." A preexisting problem such as urinary frequency may cause incontinence from decreased mobility.

Because symptoms often correlate poorly with the actual voiding problem, it is best not to initiate pharmacological or surgical treatment based solely on symptoms. Katz and Blaivas (77), in a prospective study of 425 consecutive patients, found that the clinical assessment based on symptoms did not correlate with the objective urodynamic findings in 45% of patients thought to have storage problems, in 25% believed to have emptying problems, and in 54% of those believed to have storage and emptying problems. It has also been well documented that urodynamics should be included in the evaluation of those with SCI since bladder and sphincter function cannot be predicted by history and physical examination. Ouslander et al. (78) found in the geriatric female population that presenting symptoms were predictive of the urodynamic diagnosis in only 55% of those with pure urge incontinence. It has also been well documented that urodynamics is essential in the evaluation of those with SCI since bladder and sphincter function cannot be predicted by history and physical examination (79).

Significant past history includes additional medical problems that may contribute to present problems, such as diabetes, previous CVAs, hypertension, and use of diuretics. The past history also needs to focus on surgery that may affect voiding, such as previous transurethral resection of the prostate, surgery for stress incontinence, or pelvic surgery. Questions about past and present bowel and erectile function should be asked. Potentially reversible causes of voiding disorders need to be investigated. A helpful mnemonic coined by Resnick and Yalla (80) to describe the reversible causes of incontinence in the elderly is *DIAPPERS*. These same factors also may be responsible for problems with retention. The mnemonic can be broken down as follows:

- Delirium
- Infection
- Atrophic vaginitis, urethritis
- Pharmaceuticals
- Psychological

Endocrine  
Reduced mobility  
Stool impaction

The physiatric history that has particular significance for voiding dysfunction is hand function, dressing skills, sitting balance, ability to perform transfers, and ability to ambulate. These factors not only play a role in why a person may be incontinent but also are important considerations in developing management strategies.

### Neurolgic Examination

The neurolgic physical will not give objective evidence about the bladder and sphincter function but may suggest potential contributory causes of a voiding dysfunction. The examination should focus on the abdomen, external genitalia, and perineal skin. The rectal examination is important to evaluate for cancer. Prostate obstruction cannot be determined by prostate size alone since it is not the overall size of the prostate but the amount of prostate growing inward that causes obstruction. Therefore, a urodynamic study, which measures the actual pressure within the bladder during a contraction and the resulting flow of urine, is important to objectively diagnose outflow obstruction.

In postmenopausal women, the urethra and vaginal introitus should be examined for atrophic changes suggestive of estrogen deficiency. In women, the examination also should focus on the degree of pelvic support. A determination of masses producing extrinsic compression on the bladder should be made during the vaginal examination.

The mental status portion of the neurolgic examination should, as a minimum, evaluate the patient's level of consciousness, orientation, speech, long- and short-term memory, and comprehension. Voiding disorders may be secondary to or made worse by disorientation, inability to communicate the desire to void, or lack of understanding when the patient is told to void.

The sensory examination should focus on determining the level of injury in those with SCI. Especially important is establishing whether the level of injury is above T6, which would make the patient prone to autonomic dysreflexia. Sacral sensation evaluates the afferent limb (i.e., pudendal nerve) of the sacral micturition center. Loss of pinprick and light touch sensation in the hands and feet is suggestive of a peripheral neuropathy.

The motor examination helps establish the level of injury and degree of completeness in those with SCI. Hand function should be assessed to determine the ability to undress or possibly perform intermittent catheterization (IC). Upper- and lower-extremity spasticity with sitting, standing, and ambulating also needs to be evaluated. Anal sphincter tone is also important. Decreased or absent tone suggests a sacral or peripheral nerve lesion, whereas increased tone suggests a suprasacral lesion. Voluntary contraction of the anal sphincter tests sacral innervation, suprasacral integrity, and the ability to understand commands.

Cutaneous reflexes that are helpful to the neurolgic examination are the cremasteric (L1 to L2), bulbocavernosus

(S2 to S4), and anal reflex (S2 to S4). Absence of these cutaneous reflexes suggests pyramidal tract disease or a peripheral lesion. The bulbocavernosus reflex is a useful test to evaluate the sacral reflex arc. However, it may be unreliable. A false negative often results from a person being nervous and already having his or her anal sphincter clamped down at the time of the examination. Muscle stretch reflexes also should be evaluated. A sudden increase in spasticity may indicate a urinary tract infection (UTI). In addition, pathologic reflexes (e.g., Babinski reflex) may help localize the neurologic lesion.

## UROLOGIC ASSESSMENT OF THE UPPER AND LOWER URINARY TRACT

### Indications for Testing

A variety of tests can be performed to evaluate the upper and lower urinary tract. The exact types of tests and follow-up depend on the disease process, the patient's clinical course, and any preexisting urologic problems needing further follow-up.

If the disease process is one that is not known generally to affect the upper tracts, such as a stroke, hip replacement with retention, or peripheral neuropathy, then the evaluation can be directed at the lower urinary tract. Evaluation of the upper tracts in these individuals should be undertaken if there is any suggestion of upper-tract involvement, such as pyelonephritis or hematuria.

Patients with disease processes that may affect the upper tracts, such as multiple sclerosis, should undergo baseline testing of the upper tracts and then periodic screening. Emphasis otherwise is directed primarily at the lower tract with the use of urine analysis, culture and sensitivity, postvoid residual, and urodynamics. Testing usually is done annually, but may be needed more or less frequently depending on the patient's clinical course.

Spinal cord-injured patients, particularly those with potential high intravesical voiding pressures, need constant surveillance of the upper tracts as well as lower tracts. Although there is no agreement on exactly which tests and the frequency at which testing should be done, there is agreement that upper- and lower-tract testing is necessary. The American Paraplegia Society has developed recommendations for the urologic evaluations of those with SCI (81).

Institutions often will have SCI patients undergo a yearly evaluation for the first 5 to 10 years, and if their upper tracts are stable, then evaluations are every other year. However, there is evidence that bladder function continues to change even after 20 years postinjury, suggesting that yearly evaluations should be considered (82). People with an indwelling suprapubic or Foley catheter often will get yearly cystoscopy to rule out stones and bladder tumors.

### Specific Upper- and Lower-Tract Tests

Tests designed to evaluate the upper tracts include an intravenous pyelogram (IVP), renal ultrasound, 24-hour urine

creatinine clearance, and quantitative mercaptoacetyltriglycine (MAG) 3 renal scan and computerized tomography (CT). When ordering a test one must consider whether the information is needed about the function of the upper tracts or about the anatomy of the upper tracts. For example, a renal ultrasound is excellent to detect anatomical changes; however, it will not suggest any problems with renal function until hydronephrosis develops. Conversely, a renal scan detects stasis of the upper tracts before hydronephrosis develops, but is unlikely to detect a small kidney stone.

A 24-hour urine creatinine clearance and quantitative renal scan evaluate upper-tract function, whereas renal ultrasound and CT are used to evaluate upper-tract anatomical features. An IVP evaluates both function and anatomy. Despite evaluating both function and anatomy, there are a number of disadvantages to an IVP. These disadvantages include potential allergic reactions, radiation exposure, and patient inconvenience, specifically getting an IVP laxative preparation the night before the test. Therefore, IVP is used infrequently.

The primary purpose of quantitative MAG 3 radioisotope renal scan is to monitor renal function and drainage. It has been found to be a safe and effective modality in those with SCI (83,84). While serum creatinine and creatinine clearance are easy to obtain and inexpensive, there are a number of possible problems when using them to monitor kidney function in those with SCI (85). Since individuals with SCI frequently have less muscle mass than able-bodied individuals, their serum creatinine should be less than that of able-bodied individuals. Therefore, a normal serum creatinine lab value may actually represent a high value for those with SCI. In addition, serum creatinine will not rise until there is at least a 50% decline in renal function. When ordering a 24-hour urine collection be aware that overcollection of urine (>24 hours) will overestimate kidney function and undercollection will underestimate kidney function (85).

The renal ultrasound is helpful for detecting hydronephrosis and kidney stones. When evaluating renal anatomy, ultrasound has largely replaced IVP (86). The major advantages of ultrasound are that it is noninvasive and does not involve any contrast agents. The major disadvantages of ultrasound are that it is user-dependent and does not show renal function (87).

If further anatomic definition is needed to evaluate for stones or tumors, CT should be considered. It has largely replaced IVPs in a number of institutions. In a prospective study of nonenhanced helical CT scans versus IVP, CT correctly identified 36 of 37 ureteral stones with one false positive. CT had a sensitivity 97%, specificity of 96%, and accuracy of 97% at detecting ureteric stones. This was double that of IVP (88).

Tests to evaluate the lower tracts include cystogram, cystoscopy, and urodynamics. Because each of these involves instrumentation, it is best to obtain a urine culture and sensitivity test, and give antibiotics if positive before the testing. An untreated infection or bacterial colonization has the potential to cause bacteremia and increased bladder overactivity.

Some indications for cystoscopy in those with voiding disorders include hematuria, recurrent symptomatic UTIs, recurrent asymptomatic bacteriuria with a stone-forming organism (i.e., *Proteus mirabilis*), an episode of genitourinary sepsis, urinary retention or incontinence, pieces of eggshell calculi obtained when irrigating a catheter, and long-term indwelling catheter. Cystoscopy also is indicated when one is removing an indwelling Foley catheter that has been in place for more than 2 to 4 weeks or changing to a different type of management, such as IC or a balanced bladder. Cystoscopy can reveal a pubic hair or eggshell calculus that may be missed on radiography and serve as a nidus for bladder stones.

## Urodynamics

Urodynamics provides objective information on voiding function (Table 51-2).

Urodynamics in general terms is defined as the study of normal and abnormal factors in the storage, transport, and emptying of urine from the bladder and urethra by any appropriate method (40). When deciding on an appropriate urodynamic test, one needs to consider whether information is needed about the filling phase, emptying phase, or both phases of micturition.

The following are some of the more common indications for an urodynamics evaluation:

- Recurrent UTIs in a patient with neurogenic bladder
- Urinary incontinence
- Urinary frequency
- Large postvoid residuals (i.e., retention)
- Deterioration of the upper tracts
- Monitoring of voiding pressures
- Evaluation and monitoring of pharmacotherapy

The physician's presence is important to help direct the urodynamics study. Typical decisions include how much water to put in the bladder, whether to repeat the study, and whether to have the patient sit or stand to void. Observing the patient during urodynamics also will help in getting an idea of factors that might influence the test, such as patient anxiety or inability to understand when told to void.

Blood pressure monitoring is particularly important in SCI patients prone to autonomic dysreflexia. Urodynamics is particularly helpful for detecting autonomic dysreflexia in men with SCI at T6. Autonomic dysreflexia may occur with bladder distention or more commonly when bladder distention provokes an uninhibited contraction. This causes the sphincter to contract, which causes a significant rise in blood pressure and other symptoms of autonomic dysreflexia. However, 43% of the men with SCI at T6 and above may have "silent dysreflexia" (elevated BP without any symptoms) during voiding. This would not be detected without urodynamics and simultaneous blood pressure monitoring (89).

In order to have an accurate urodynamic evaluation, it is important that a person does not have a UTI. Bladder wall inflammation is likely to cause the bladder to lose some of its compliance, resulting in a smaller bladder capacity than normal.

The inflammation is also likely to trigger uninhibited contractions and cause the bladder to be more overactive than usual. A recent prospective study found that 9.7% of SCI individuals who had asymptomatic bacteriuria developed a symptomatic UTI post testing. Nearly 40% of SCI individuals with sterile urine developed asymptomatic bacteriuria post testing (90).

It would be expected that one or two doses of an antibiotic would clear the bacteria from the urinary tract and reduce the risk of an infection. However, it has been our practice to obtain a urine culture and sensitivity 1 to 2 weeks prior to the test. Those with pyuria or a symptomatic UTI are treated for 5 days prior to testing with the goal not only to eradicate the bacteria in the bladder but also to give adequate time to reduce inflammation of the bladder wall. Those with sterile urine or asymptomatic bacteriuria are given one or two doses of an antibiotic prior to testing. A person who presents for testing with cloudy urine or other symptoms of a UTI is rescheduled.

### Evaluation of Bladder Filling (Storage Phase)

The simplest type of bladder test to evaluate bladder filling is known as a bedside cystometrogram. This test involves attaching a cylinder such as 50 mL filling syringe without the plunger to a Foley catheter. Water is then poured into the cylinder and allowed to drain by gravity into the bladder. The blood pressure and volume of fluid going into the bladder are recorded. The Foley is sometimes attached by means of a Y-connector to a manometer, which is used to measure the actual rise in water pressure. This test can be used to evaluate sensation (whether or not a person is aware of the bladder being filled), stability (whether or not there is a rise in the column of water signifying a bladder contraction), and capacity (the volume at which the bladder contraction occurs). It can also be used as a screening test to determine if an SCI patient has come out of spinal shock. There are several limitations to the bedside cystometrogram, however. It is difficult to determine if small rises in the water column result from intra-abdominal pressure (i.e., straining) or a bladder contraction. An iatrogenic bladder contraction can be elicited if the tip of the Foley catheter rubs against the trigone pressure sensors, which can then trigger bladder contractions. Most important, the voiding phase cannot be evaluated (91).

The carbon dioxide urodynamics has been largely replaced with water-fill urodynamics. Although the gas is cleaner and neater to use than water, the major disadvantage is that the voiding phase of micturition cannot be evaluated. Therefore, this test is of little use when trying to evaluate bladder and sphincter function during emptying.

### Evaluation of Bladder Emptying

One of the easiest screening tests to evaluate bladder emptying is a postvoid residual; however, it should not be used to characterize the specific type of voiding dysfunction. The postvoid residual can be determined with catheterization or bladder ultrasound. A younger person should have no postvoid residual; however, an elderly person with no voiding symptoms may

have a postvoid residual of 100 to 150 mL. A normal postvoid residual does not rule out a voiding problem. For example, a postvoid residual may be normal despite significant outflow obstruction (e.g., benign prostate hypertrophy, sphincter-detrusor dyssynergia) as a result of a compensatory increase in the strength of detrusor contractions or of absent bladder contractions in the presence of increasing intra-abdominal pressure (e.g., Valsalva maneuver, Crede maneuver). Caution also has to be taken in interpreting a large postvoid residual. It may be abnormal because it was not taken immediately after voiding, because of poor patient understanding, or because of an abnormal voiding situation (e.g., the patient was given a bedpan at 2:00 A.M.).

A multichannel water-fill urodynamic study is the gold standard to evaluate bladder function because it measures both the filling and the emptying phase of micturition. Multichannel refers to the fact that each of the various urodynamics parameters is measured as a separate channel such as detrusor pressure, abdominal pressure, and flow rate. Urodynamic studies also may incorporate urethral pressure recordings, urethral sphincter or anal sphincter EMG, videofluoroscopy, and the use of various pharmacologic agents, such as bethanechol (Fig. 51-4).

**FIGURE 51-4.** Waterfill urodynamics setup. Simultaneous monitoring of various urodynamics parameters is shown. Intravesical pressure minus intra-abdominal pressure will produce the detrusor pressure ( $P_{det}$ ). **A:** Intravesical pressure,  $P_{ves}$ . **B:** Urethral sphincter pressure,  $P_{ur}$ . **C:** Urethral sphincter electromyography. **D:** Intra-abdominal pressure,  $P_{abd}$ . **E:** Urine flow rate.

### Multichannel Water-fill Urodynamic Study

A water-fill urodynamic study evaluates two distinct phases of bladder function. The first is the filling (storage) phase, during which water is being infused into the bladder. Urodynamic parameters that can be evaluated during this phase include bladder sensation, bladder capacity, bladder wall compliance, and bladder stability (whether or not there are uninhibited contractions). The second portion of the study is the voiding (emptying) phase. The voiding phase is considered to begin when a person is told to void. In those who have neurogenic bladders and reflexly void, the voiding phase is considered to begin when the person has an uninhibited contraction and voiding begins. Urodynamic parameters that can be evaluated during the voiding phase include opening or leak-point pressure (bladder pressure at which voiding begins), maximum voiding pressure, urethral sphincter activity (EMG or actual pressure), flow rate, voided volume, and postvoid residual. In those who have the potential for autonomic dysreflexia, changes in blood pressure before, during, and after voiding can also be evaluated.

With an empty bladder, there should be no sensation of fluid within the bladder. During the filling phase, the first sensation that a person has of having a full bladder (first sensation of fullness) usually occurs with 100 to 200 mL within the bladder. The sensation of fullness occurs around 300 to 400 mL, and the onset of urgency usually occurs between 400 and 500 mL. There is, however, variability in bladder capacity, which ranges between 400 and 750 mL in adults. There should be little to no rise in the intravesical pressure, which indicates normal bladder wall compliance. Additionally, there should be no involuntary bladder contractions during this part of the study.

During the voiding phase, the detrusor pressures usually are less than 30 cm H<sub>2</sub>O in women and between 30 and 50 cm H<sub>2</sub>O in men. A normal maximum flow rate is 15 to 20 mL/s and should not be less than 10 mL/s in any age group. The patient should have at least 150 mL in the bladder because the flow rate depends on the voided volume (44). The flow usually has a bell-shaped curve, progressively increasing to its maximum rate and then decreasing. The urethral sphincter should remain open throughout voiding, and there should be no rises in intra-abdominal pressure during voiding. As previously discussed, there should be no postvoid residual, although postvoid residuals increase with age.

A single elevated postvoid residual during urodynamics should be interpreted with caution because the patient may be nervous and voluntarily stop the urine stream. Several catheterized or ultrasound postvoid residual tests should be done to confirm an increased urodynamic postvoid residual (Fig. 51-5). Urodynamics is able to characterize specific types of voiding patterns (Fig. 51-6).

### Special Considerations in Children

At one time, urodynamic evaluation was delayed until a child was school-aged and definitive corrective surgery was to be performed. However, reflux and renal deterioration often occur during the first 3 years of life. McGuire and colleagues

**FIGURE 51-5.** Normal urodynamic findings. There is a minimal rise in intravesical pressure during the filling phase. The voiding phase is initiated with quieting of EMG activity, and relaxation of the external urethral sphincter is followed by a bladder contraction. **A:** Intravesical pressure ( $P_{ves}$ ). **B:** Urethral sphincter pressure ( $P_{ur}$ ). **C:** Urethral sphincter electromyography. **D:** Intra-abdominal pressure ( $P_{abd}$ ). **E:** Urine flow rate.

reported that there was a high incidence of renal deterioration in patients with urethral leak-point pressures greater than 40 cm H<sub>2</sub>O (92). Therefore, it is recommended that all myelodysplastic newborn children be evaluated as soon as possible (93).

It is difficult to obtain high-quality water-fill urodynamic studies on children younger than 4 or 5 years old. In younger children, it sometimes is necessary to use sedation or general anesthesia. It is important that children feel comfortable with the physician, nurses, and test. As a general principle, the amount of additional information gained from insertion of EMG needles usually is not enough to warrant the risk of obtaining poor urodynamics results from a crying, fearful child. This is especially true if it is anticipated that the child will come back for follow-up studies.

## MANAGEMENT OF VOIDING DYSFUNCTIONS

A useful way to organize management of voiding dysfunctions is to base treatment options on a modification of the Wein classification: incontinence caused by (a) the bladder

**FIGURE 51-6.** Schematic representation of various voiding patterns. **A:** Normal. **B:** Uninhibited contractions occur with filling. The sphincter is attempting to inhibit contractions. The patient has a normal voiding phase. **C:** No bladder contractions. Rises in bladder pressure result from rises in abdominal pressure (i.e., Valsalva voiding). **D:** Uninhibited contractions occur with simultaneous sphincter contractions (i.e., detrusor sphincter dyssynergia).  $P_{abd}$ , intra-abdominal pressure;  $P_{ur}$ , urethral sphincter pressure;  $P_{ves}$ , intravesical pressure.

or (b) the outlet (e.g., bladder neck, sphincter, or prostate) or retention caused by (a) the bladder or (b) the outlet. Management can be categorized as behavioral, pharmacological, surgical, or supportive. Table 51-3 shows various treatment options. Although each of these modalities is listed separately, it is important to note combinations within the same category (e.g., behavioral—timed voiding, fluid restriction, biofeedback) and separate categories (e.g., behavioral—timed voiding, pharmacologic—anticholinergics).

It is important to characterize the type of voiding dysfunction that a person has with an urodynamics evaluation, particularly

**TABLE 51.3** Treatment Options for Voiding Disorders

**Incontinence Caused by the Bladder**

*Behavioral:* Scheduled (timed) voiding, limited fluid intake, biofeedback

*Pharmacologic:* Oral anticholinergics, antispasmodics, tricyclic antidepressants, DDAVP (Vasopressin), intravesical oxybutynin, intravesical C-fiber afferent neurotoxins (capsaicin, resiniferatoxin),<sup>a</sup> calcium antagonists,<sup>a</sup> prostaglandin inhibitors<sup>a</sup>

*Surgical:* Augmentation cystoplasty, urinary diversion, interruption of innervation, neurostimulation, botulinum toxin injections into the bladder wall<sup>a</sup>

*Supportive:* Diapers, external condom catheter, intermittent catheterization, indwelling catheter

**Incontinence Caused by the Sphincter**

*Behavioral:* Scheduled voiding, pelvic floor exercises, biofeedback

*Pharmacologic:* Alpha-adrenergic agonists, estrogen, injectable periurethral bulking agent

*Surgical:* Artificial sphincter, urethral suspension, neurostimulation<sup>a</sup>

*Supportive:* Same as with bladder

**Retention Caused by the Bladder**

*Behavioral:* Scheduled voiding (↓ cognition/mobility), suprapubic tapping (bladder hypocontractility), Valsalva, Credé

*Pharmacologic:* Cholinergic agonists, intravesical prostaglandin,<sup>a</sup> narcotic antagonists<sup>a</sup>

*Surgical:* Sphincterotomy, neurostimulation (if bladder contraction present)

*Supportive:* Intermittent catheterization, indwelling catheter

**Retention Caused by the Sphincter/Outlet**

*Behavioral:* Biofeedback, suprapubic tapping, anal stretch/scissoring

*Pharmacologic:* Alpha-adrenergic blockers, baclofen, diazepam, dantrolene

*Surgical:* Sphincterotomy, botulinum toxin injections, pudendal neurectomy, bladder outlet surgery, urethral stents, balloon dilation<sup>a</sup>

*Supportive:* Same as with bladder

<sup>a</sup>Investigational use.

when considering pharmacological and surgical options (see Table 51-3). In addition to the type of voiding dysfunction, the physician needs to consider the type of disease process (i.e., progressive, stable, or remitting), cognition, mobility, family support, and medical conditions when recommending a bladder-management program. Empirical pharmacotherapy should be discouraged because there is a risk of potential side effects of drugs that may have no benefit or make the problem worse.

The following are goals of management in patients with voiding dysfunctions:

Prevent upper-tract complications (e.g., deterioration of renal function, hydronephrosis, renal calculi, pyelonephritis).

Prevent lower-tract complications (e.g., cystitis, bladder stones, vesicoureteral reflux).

Develop a bladder management program that will allow patient to reintegrate most easily back into the community.

### Therapy for Incontinence Caused by the Bladder Behavioral Treatment Options

Many patients with incontinence caused by the bladder benefit from a scheduled (timed) voiding regimen. Patients with incontinence resulting from poor cognition, aphasia, or poor mobility but normal bladder function often are also helped by being placed on a commode or offered a urinal at set intervals. This is known as timed voiding. Patients who have an overactive detrusor may decrease incontinent episodes by voiding by the clock rather than waiting for a sense of fullness. They are taught to void before reaching their full bladder capacity because uninhibited contractions often become more forceful and frequent as the bladder is reaching its full capacity. Once the contraction begins it is very difficult to get undressed and go to the bathroom in time.

Another type of behavioral intervention is bladder training. This is done by progressively increasing the time between voiding by 10 to 15 minutes every 2 to 5 days until a reasonable interval between voiding is obtained (94). Bladder training often is effective for a person who has recovered or is recovering from a neurologic lesion (e.g., head injury, stroke) with improved bladder function but is voiding frequently out of habit or from fear of incontinence based on past experience.

### Pharmacological Treatment Options

Pharmacologic treatment often is needed in addition to timed voiding in patients with incontinence caused by detrusor overactivity. There are currently a wide variety of medications available, which have anticholinergic effects. If a person does not tolerate one type of anticholinergic, he or she may tolerate another type of anticholinergic medication. Anticholinergic agent's primary action is to block acetylcholine receptors competitively at the postganglionic autonomic receptor sites. Some agents, such as oxybutynin, also have a localized smooth-muscle antispasmodic effect distal to the cholinergic receptor site and a local anesthetic effect on the bladder wall (95). Some of the more common potential side effects of anticholinergic medications include dry mouth, pupillary dilatation and blurred vision, tachycardia, drowsiness, and constipation from decreased gastrointestinal motility. Newer anticholinergic agents have been developed to be more selective to the bladder receptors, or have a slow sustained release or topical patch developed in an attempt to lessen anticholinergic side effects, particularly dry mouth and constipation. It has not been shown whether these agents maintain their effectiveness for an entire 24-hour period. Twenty-four-hour effectiveness is important in those with SCI at or above T6 who have the potential to develop autonomic dysreflexia if their medications "wear off" and they begin to develop uninhibited contractions. In those with neurogenic bladders the object is frequently to

completely shut down the bladder and cause retention so IC can be performed. Therefore, those with neurogenic detrusor overactivity often require more than the "standard" doses used for able-bodied individuals.

Tricyclic antidepressants sometimes are used alone or in combination with anticholinergic agents. These medications are thought to have a peripheral anticholinergic effect and a central effect. They have been found to suppress uninhibited bladder contractions, increase bladder capacity, and increase urethral resistance (96). There have been several reports of severe autonomic dysreflexia in SCI patients secondary to overdistention of the bladder with urine. Therefore, caution should be taken in giving these medications that depend on uninhibited contractions to void (reflex voiders).

Intravesical instillation of medications is sometimes used because oral anticholinergic medications have a number of side effects. The major advantage of intravesical medications is that there are minimal to no systemic side effects due to less systemic absorption from the bladder wall. This is particularly helpful for those with a neurogenic bowel, because anticholinergic medications frequently cause constipation that could lead to fecal impaction. Anticholinergic medications may also cause a dry mouth, which can be particularly difficult to tolerate for those trying to limit their fluids because of being on IC.

Intravesical lidocaine has been shown to be effective at suppressing uninhibited bladder contractions in those with overactive bladders (97). Although it has a rapid onset of action, it does not have a long duration of action. Therefore, this medication is best reserved for use in acute problems. For more long-term suppression of uninhibited bladder contractions, oxybutynin can be used for intravesical instillation (98). It not only has an anticholinergic effect but also a topical anesthetic effect. This medication is effective at suppressing uninhibited bladder contractions, but it still has the disadvantage of only being effective for 4 to 6 hours. One study reported using 5 to 10 mg dissolved in 15 to 30 mL of normal saline instilled into the bladder three to four times a day; this dose noted in the seven men resulted in an improvement in body image and enhanced sexuality because of the significant improvement in incontinence (99). Another investigator examined 32 patients, comparing standard dosages of intravesical oxybutynin (0.3 mg/kg body weight per day) with increasing dosages in steps of 0.2 mg/kg body weight up to 0.9 mg/kg body weight per day. Twenty-one of thirty-two (66%) patients became continent with the standard dose. Seven of the eleven failures at the lower dose became continent with a median dose of 0.7 mg/kg body weight for an overall success rate of 28 of 32 (87%). Four of the eleven (12.5%) had no improvement, and two of the eleven patients had side effects with a dosage of 0.9 mg/kg body weight per day (100). Despite its effectiveness, a number of individuals abandon using intravesical instillations because it is so labor intensive.

Intravesical instillations may, however, assume a more important role of helping to control uninhibited contractions with the development of longer-acting agents. Of particular interest is afferent C-fiber neurotoxins. The prototype

medication is capsaicin, which is effective at suppressing uninhibited contractions for several months at a time (101). Unfortunately, capsaicin frequently causes discomfort or suprapubic pain, urgency, hematuria, and autonomic dysreflexia, which can last to up to 2 weeks postinstillation.

A newer afferent C-fiber neurotoxin, resiniferatoxin, is being investigated. It is 1,000 times stronger than capsaicin and is long-acting. It has an extremely rapid onset of action at desensitizing the C-fiber afferent neurons, which causes minimal discomfort when it is instilled. In a study, 14 patients with detrusor hyperreflexia were instilled with 100 mL (or the bladder capacity if lower than that volume) of 50 to 100 nm resiniferatoxin instillation in 10% alcohol in saline. Treatment improved or abolished incontinence in 9 of 12 (75%) patients. Mean cystometric capacity increased from 182 to 330 mL. Maximal detrusor pressure was not modified by treatment. The effects were long-lasting, up to 12 months in seven patients (102). It is our understanding that Food and Drug Administration (FDA) multicenter trials evaluating resiniferatoxin in the United States have been stopped due to funding issues.

Desmopressin acetate has been found to decrease the number of episodes of nocturia in patients with multiple sclerosis. However, further studies are needed to determine its usefulness in the elderly because of the high prevalence of contraindications such as renal insufficiency, heart failure, and risks of inducing hyponatremia and fluid retention (29).

Another modality that has been gaining increasing popularity to help suppress uninhibited contractions in those with an overactive bladder is botulinum-A toxin injected into the bladder wall. While there have been encouraging data from early open-labeled and randomized, controlled trials with regards to efficacy and tolerability in both nonneurogenic and neurogenic bladder overactivity, the most experience has been with neurogenic bladder overactivity (103–105). Botulinum toxin inhibits acetylcholine release at the neuromuscular junction, which in turn blocks neuromuscular contraction and relaxes muscles that are either spastic or overactive. Doses ranging between 100 to 300 units have been confirmed by cystometry to suppress an overactive detrusor (103–105). Because it may take 1 to 4 weeks to completely deplete the acetylcholine at the neuromuscular junction, maximal effects at quieting the bladder do not occur immediately. Since there is reinnervation and sprouting at the neuromuscular junctions, the effects usually wear off after 3 to 6 months, so the injections usually need to be repeated. It appears that injections into the bladder wall may last closer to 6 months. Recent systematic reviews confirmed that botulinum toxin injections into the detrusor provide a clinically significant improvement in adults with neurogenic detrusor overactivity and incontinence refractory to other pharmacological therapy. It was well tolerated. The reviews point out that more studies are needed to evaluate issues such as the optimal dose, number and location of injections, and duration of effect (103–105). The panel for the SCI Consortium Guidelines on Management For Adults with SCI listed the use of botulinum injections into the bladder

(detrusor) muscle as a bladder management option for those with SCI on IC with detrusor overactivity (106). Botulinum toxin to treat detrusor-sphincter dyssynergia is discussed in the pharmacologic agent section “Therapy for Retention Caused by the Outlet or Sphincter.”

In summary, there is a wide variety of pharmacologic agents that may be used by themselves or in conjunction with treatment modalities. A number of pharmacological agents discussed in this section as well as in the following sections are still undergoing investigation or “off-label” use. One reason is that individuals with “neurogenic bladders” are frequently excluded from initial FDA trials or do not make up a large enough population to have drug companies initiate trials in those with SCI. When using any pharmacologic agents for treatment, potential side effects and contraindications must be weighed against potential benefits.

### **Surgical Treatment Options** **Bladder Augmentation**

Bladder augmentation is a surgical technique that is frequently used to create a large bladder capacity with low intravesical pressures. Because this is a surgical procedure, other alternatives, such as pharmacologic treatment, should first be tried.

Surgical treatment is sometimes needed to improve bladder capacity in adult patients who are incontinent and want to perform IC. The SCI Consortium Bladder Management Panel recommended that bladder augmentation be considered for individuals with SCI who have (a) intractable involuntary bladder contractions causing incontinence, (b) the ability and motivation to perform IC, (c) the desire to convert from reflex voiding to an IC program, (d) a high risk for upper-tract deterioration secondary to hydronephrosis and/or ureterovesical reflux as a result of high-pressure detrusor-sphincter dyssynergia (106). They also recommended to consider avoiding bladder augmentation in individuals with (a) inflammatory bowel disease, (b) pelvic irradiation, (c) severe abdominal adhesions from previous surgery, and (d) compromised renal function (106).

An extensive preoperative evaluation is important. The history should include questions about any gastrointestinal problems. Urodynamics should be done to evaluate bladder and sphincter function. Various treatments may be needed to treat the sphincter if there is a low leak point pressure. Screening laboratory work should include liver and renal function. To help reduce the risk of significant acidosis and metabolic abnormalities, bladder augmentation is best reserved for those with serum creatinine less than 2.0 mg/dL. A cystogram should be done to evaluate for vesicoureteral reflux. Ureteral reimplantation may be considered if there is significant reflux. Upper-tract evaluation is important both to rule out any problems and to serve as a baseline for follow-up post augmentation (107).

There are a number of different techniques of bladder augmentation in which different segments of bowel can be used. The most common type of bladder augmentation is the clam cystoplasty. This procedure involves isolating a piece of

intestine, being careful to keep it attached to its mesentery, detubularizing it, and sewing it onto the bladder, which is first partially bivalved. Various bowel segments can be used and depend on the surgeon's preference.

There are predictable metabolic abnormalities depending on the segment being used. The stomach mucosa has secretory epithelium with little resorptive function. Gastric mucosa secretes hydrochloric acid in conjunction with systemic bicarbonate release. Therefore, hypochloremic metabolic alkalosis can result if the stomach is being used, particularly if there is poor renal function. However, the stomach has the least absorptive properties and is best if one is concerned about metabolic acidosis from reabsorption of urinary solutes through the bowel wall. However, this is technically more difficult than an intestinal segment closer to the bladder.

The jejunal mucosa is different from the ileum and large intestine in that it secretes sodium and chloride and may result in hyponatremia, hypochloremia, and hyperkalemia. This segment is most likely to result in metabolic abnormalities and rarely used in diversions. The ileum and colon have similar transport mechanisms. Ammonia and chloride are reabsorbed. This can lead to hyperchloremic metabolic acidosis.

The most frequent changes that occur after this are an increase in mucus noted in the urine, possible metabolic changes, abnormal drug absorption (especially those that are absorbed by the gastrointestinal tract and excreted unchanged by the kidneys, such as Dilantin and certain antibiotics), osteomalacia from chronic acidosis, and stones, particularly in those with urea-splitting organisms and hyperchloremic metabolic acidosis. Long-term consequences of bowel attached to bladder are unknown. There have also been case reports of cancer in those with bladder augmentations, ileal conduits, and colon conduits. These have been adenocarcinomas, undifferentiated carcinomas, sarcomas, and transitional cell carcinomas (108–114). There have been a few reports of patients who had an augmentation cystoplasty more than 10 years previously developing adenocarcinoma in the bladder (110).

Mast and associates reported a 70% success rate at stopping incontinence (mean length of follow-up 1.5 years), and this was increased to 85% with the addition of an artificial sphincter in those with low sphincter resistance (111).

Complications included recurrent UTI (59%) and stone formation (22%). As a result of complications, however, further surgery was required for 44% of the patients. Another study evaluated clinical outcome and quality of life after enterocystoplasty in 18 patients with neurogenic bladders and 3 with contracted bladders because of radiation cystitis (112). Enterocystoplasty was performed using a 40-cm segment of terminal ileum. Mean bladder capacities improved from 165 mL preoperatively to 760 mL postoperatively. At a mean of 36 months, 90% had acceptable continence rates and 95% reported improved quality of life (112).

### ***Bladder Autoaugmentation***

Another method of surgically increasing bladder size without mucus formation and use of a bowel segment is a bladder

autoaugmentation. This is also called a detrusor myomectomy. Through an abdominal approach, the bladder muscle is stripped away from the inner mucosal lining. Without this muscle lining, the bladder mucosa gradually stretches to become a large diverticulum, thus increasing bladder capacity. Autoaugmentation has the advantage of not causing metabolic and absorption problems as described previously for bladder augmentation using a bowel segment. However, this procedure is often technically difficult, particularly in those with a neurogenic bladder who frequently have a small, a heavily trabeculated bladder, and it offers only an approximate 25% increase in bladder capacity. The capacity does not immediately increase, but gradually increases over time. One investigator reported on bladder autoaugmentation of 50 men with neurogenic bladders. Bladder capacity increased over a period of 1 to 6 months. One patient had a bladder rupture and two were reported to have “failed” because of psychological reasons (113).

### ***Urinary Diversions***

Another method of management is urinary diversion. Although there are many types of diversions, they can be grouped into two types: standard (noncontinent) and continent diversion. Preoperative workup should be the same as that for bladder augmentation.

Noncontinent urinary diversion may be used as an alternative to augmentation cystoplasty or continent diversion when hand function does not permit self-catheterization. The most common standard noncontinent diversion is an ileal conduit. Ten to fifteen centimeters of ileum, along with its mesentery, is isolated from the ileum. The isolated segment of ileum is closed off at one end, and the other end is brought out through the abdominal wall and everted as a nipple stoma. The ureters are implanted onto the side of the ureters.

The SCI Consortium bladder panel recommended that urinary diversion be considered for individuals with SCI who have (a) lower urinary complications secondary to indwelling catheters, (b) urethrocuteaneous fistulas, (c) perineal pressure ulcers, (d) urethral destruction in females, (e) hydronephrosis secondary to a thickened bladder wall, (f) hydronephrosis secondary to vesicoureteral reflux or failed reimplant, and (g) bladder malignancy requiring a cystectomy.

The most common reason for noncontinent urinary diversions in those with SCI is to divert the urinary stream away from the perineum because of impaired healing of a decubitus because of urinary incontinence, or a urethral stricture or fistula. The panel recommended that there should be caution considering urinary diversions with in SCI individuals who are (a) too debilitated to undergo a major surgical procedure or (b) have one of the following conditions: inflammatory bowel disease, pelvic irradiation, severe abdominal adhesions from previous surgery, or (c) compromised renal function (106).

Continent diversions may be used in those who need to have their urinary stream diverted and who have adequate hand function to perform IC. Continent diversions are divided into two types. The first are orthotopic diversions, in which the

bowel reservoir is anastomosed to the urethra, and the second is a continent catheterizable pouch.

Orthotopic diversions are much like bladder augmentations and used to increase bladder capacity. Because they are attached to the urethra, people can catheterize themselves through their urethra in the same manner that they would if they were catheterizing their bladder. Continent catheterizable pouches have the advantage that the stoma can be placed in a location that makes catheterization easier. For example, the stoma can be created within the umbilicus so that a person does not have to undress to catheterize himself or herself. The most difficult part of the continent diversion is the creation of a continent mechanism.

The SCI Consortium panel recommended that a continent urinary diversion be considered in individuals with SCI; (a) in whom it is not feasible to augment the native bladder, (b) who cannot access their native urethra because of congenital abnormalities, (c) who have spasticity (making it difficult to catheterize their urethra), obesity, contracture, or tetraplegia, or who require closure of an incompetent bladder neck, (d) females with tetraplegia in whom a chronic indwelling catheter has caused urethral erosion, (e) males with SCI with unsalvageable bladders secondary to urethral fistula and sacral pressure ulcers, and (f) individuals with bladder cancer requiring cystectomy (106).

The most commonly used bowel segment for this is the ileocecal valve. The right colon without a segment of small bowel to increase volume is used for the pouch, and the terminal ileum is used to create the catheterizable limb (107,108).

Postoperatively patients need to catheterize their pouch frequently to prevent rupture. Because there is an increase in mucus, patients need to be taught how to irrigate their pouch. Irrigations can be decreased over time, but irrigation is recommended at least once a month as there may be malabsorption of bile salts because of the use of the ileal cecal valve. This increase in bile salts in the colon may cause diarrhea. This is best treated with oral administration of cholestyramine (114).

Long-term follow-up of bladder augmentations and urinary diversions includes regular monitoring of the upper tracts and careful monitoring of blood chemistries and renal function. Cystoscopy is used to monitor for stones or tumors (107,108).

Surgical methods also have been designed to interrupt innervation to the bladder. This can be done centrally (e.g., subarachnoid block, cordectomy), peripherally (e.g., anterior or anteroposterior rhizotomy), or perivesically (e.g., extensive mobilization of the bladder) (115–117). Although there usually is a successful short-term outcome, decreased compliance or detrusor hyperreflexia may return. This may result from an increased sensitivity of receptors following decentralization (24). Impotence usually occurs after these procedures.

### **Neurostimulation**

Neurostimulation is a relatively new area of research. Electrical stimulation has a number of uses in treating those with voiding

dysfunction. It has been used both to facilitate storage by decreasing uninhibited bladder contractions and to improve voiding by helping to trigger uninhibited contractions. Neurostimulation to inhibit bladder contractions has had its widest use in able-bodied individuals with overactive bladders. Ohlsson and Frankenberg-Sommar (118) reported an average 49% increase in bladder capacity by stimulation of the pudendal nerve with anal and vaginal electrode plugs. Tanago (119) reported success at selective sacral root stimulation to increase sphincter tone, which in turn suppresses detrusor activity.

In those with neurogenic bladders, investigators continue to try to improve voiding through the use of neurostimulation. Techniques include placing electrodes on the bladder itself, the pelvic nerves, conus medullaris, sacral nerves, and the sacral anterior roots. Of these, sacral anterior root stimulation has been most successful.

Brindley et al. (120) developed an anterior root stimulator that produces micturition by stimulating the sacral nerve roots. The largest experience is with surgically implanted Finetech-Brindley sacral afferent stimulator; there have been an estimated 800 implants over 15 years.

It is important to stress to patients that sacral stimulation is not indicated unless an individual has an intact sacral reflex arc and a bladder capable of having bladder contractions (106). Stimulation of the sacral afferent nerves causes reflex activation of the efferent nerves to the sphincter. However, this reflex accommodates so that fatigue of the sphincter occurs and the pressure generated in the urethra is overcome by the bladder contraction. A posterior rhizotomy is often performed at the same time as the sacral implant to abolish uninhibited bladder contractions, abolish contractions of the sphincter, and improve bladder wall compliance. The disadvantage of the posterior rhizotomy is the loss of reflex erections and reflex ejaculations, loss of perineal sensation, and loss of reflex bladder contractions (106,121). Van-Kerrebroeck reviewed the worldwide experience with the Finetech-Brindley sacral stimulator. In 184 cases, of which 170 were using the stimulator, 95% had postvoid residuals less than 60 mL. There was no deterioration of the upper tracts. Two thirds of men reported stimulated erections, but only one third used these for coitus (122). Sacral stimulation is further discussed in Chapter 65.

## **Supportive Treatment Options**

### ***Protective Undergarments***

Protective undergarments are often helpful either as primary management or as backup to management for timed voiding. Custom-fit diapers are much more cosmetic than in the past. Major drawbacks include expense, patient embarrassment, difficulty getting them on and off, and potential skin breakdowns if they are not changed within 2 to 4 hours after getting wet. Insurance companies often do not reimburse for undergarments.

### ***External Condom Catheters***

External condom catheters often are a good option for men with detrusor overactivity or normal bladder function with

incontinence secondary to mobility or cognitive factors. An external condom catheter is not recommended unless the bladder is able to contract and empty with a minimal postvoid residual (with or without treatment of the sphincter—see section Management of Urinary Retention Due to the Sphincter). An advantage of an external condom catheter over protective undergarments is that condom catheters need to be changed only once a day and are often covered by insurance plans. Major drawbacks include wearing of a leg bag, potential for penile skin breakdown, condom catheter falling off, and slight increase in bladder infections compared to those who do not wear an external condom catheter. A reliable external collecting device for women has not been developed.

### ***Intermittent Catheterization***

IC, usually also requiring pharmacological or surgical intervention, is another effective way to manage patients with detrusor overactivity and incontinence. Guttman and Frankel popularized sterile IC for SCI patients in the 1960s. They reported that in 476 SCI patients monitored over 11 years on sterile IC, only 7.4% developed hydronephrosis, 4.4% had vesicoureteral reflux, 1.7% developed kidney stones, and 0.6% developed bladder stones (123). In the mid-1970s, Lapides et al. reported on the effectiveness of IC using clean technique in those with SCI. They attributed the success of IC to keeping the bladder from getting overdistended. One reason for this was the ease of performing clean IC compared with sterile technique (requiring gloves and somewhat bulky catheter kit at the time when these studies were done) so that patients were more likely to catheterize themselves and prevent bladder overdistention than with sterile technique (124). Maynard and Glass (125) reported that 80% of patients on clean IC monitored for 60 months continued this technique, suggesting low morbidity and high patient acceptance. Since these studies, it should be noted that sterile IC has become simplified using “a sterile catheter in a bag” so there is probably no significant difference between sterile and clean “IC.”

The important principles of IC are to restrict fluids to 2 L/d and to catheterize frequently enough to keep the bladder from becoming overdistended (<500 mL). Bladder overdistention is a major cause of bladder infections.

The SCI Consortium bladder panel recommends to consider avoiding in individuals with SCI who have one or more of the following: (a) inability to catheterize themselves or a caregiver who is unable to perform catheterization, (b) abnormal urethral anatomy such as stricture, false passages, and bladder neck obstruction, (c) bladder capacity less than 200 mL, (d) poor cognition, little motivation, and inability or unwillingness to adhere to the catheterization time schedule or the fluid intake regimen, or (e) adverse reaction toward having to pass the catheter into the genital area multiple times a day, and (f) tendency to develop autonomic dysreflexia with bladder filling despite treatment (106).

Use of prophylactic antibiotics is discouraged for most individuals on IC. Antibacterial prophylaxis has been shown to significantly reduce the probability of laboratory infection but

not the probability of clinical infection, although a trend was noted toward fewer clinical infections (125). In addition to the cost and potential side effects of antibiotics, a major concern of prophylactic antibiotics is the development of resistant organisms.

### ***Indwelling Urethral Catheterization***

With shorter lengths of hospital stays, many people with SCI are discharged from the hospital while their bladder is still in “spinal shock.” Those with other rehabilitation diagnosis such as a stroke or hip replacement may have poor mobility or difficulty with dressing, which may cause urinary incontinence because of the inability to get to the bathroom in time. It has been recommended that indwelling catheterization be considered for individuals with SCI who have one or more of the following: (a) poor hand skills, (b) high fluid intake, (c) cognitive impairment or active substance abuse, (d) elevated detrusor pressures, (e) lack of success with other less invasive bladder management methods, (f) need for temporary management of vesicoureteral reflux, and/or (g) limited assistance from a caregiver, making another type of bladder management not feasible (106).

A major advantage of having an indwelling catheter is the ability to have more independence. In SCI individuals discharged home on IC, the most common reason for switching to an indwelling catheter is the inability at being independent at performing IC. One study showed that 80% of those with tetraplegia prefer an indwelling catheter for social and practical methods (126). Because there is no satisfactory external collecting device for women, an indwelling catheter is particularly useful in women with poor hand function who have urinary retention and/or urinary incontinence.

Those without SCI who are not independent at transfers and dressing and their family members also often benefit having in an indwelling catheter when initially discharged from the acute care hospital. The indwelling catheter allows the family to deal with one less issue as the person is recovering and getting stronger. A common misconception is that the indwelling catheter causes a person to develop a “lazy bladder” or forget how to void. The opposite is actually true. The indwelling catheter increases a person’s bladder tone, especially if he or she has had a situation of chronic overdistention.

The above considerations may be used for those without SCI. In the elderly and those with nonneurogenic bladders, the Centers for Medicare and Medicaid Services (CMS) Guidance Tag F-315 emphasize that there must be a medically justified reason for an indwelling catheter in place for more than 14 days. These reasons include (a) documented PVR are in a range over 200 mL, (b) inability to manage the incontinence/retention with IC, (c) persistent overflow incontinence, (d) symptomatic infections, and/or renal dysfunction, (e) contamination of stage 3 or 4 pressure ulcers with urine that has impeded healing, and (f) terminal illness or severe impairment that makes positioning or clothing changes uncomfortable or that is associated with intractable pain (127).

Principles of management of an indwelling urethral (Foley) catheter include (a) an oral fluid intake of at least 2 L/d unless there is a medical reason for fluid restriction, (b) keeping the catheter taped up to the abdomen of men when they are lying down to decrease the risk of a hypospadias due to downward pulling off the catheter during an erection, (c) daily cleaning the urethral meatus of incrustations with soap and water, (d) preventing reflux of urine into the bladder by not raising the drainage bag above the level of the bladder, (e) allowing effective urine drainage into the leg bag by not allowing the leg bag get more than half full, and (f) changing the Foley catheter every 2 to 4 weeks. In those with frequent encrustations, weekly catheter changes may be helpful. Catheter size should be limited to 14 to 16 Fr, especially in women. There is concern that larger diameter catheters may cause urethral dilatation and possible erosions. Health care providers will sometimes put in larger diameter catheters in women in an attempt to prevent leaking around the catheter rather than treating the cause (i.e., UTIs, detrusor overactivity). While the larger catheter may temporarily help the problem, the urethra frequently becomes dilated and the leaking around the catheter reoccurs.

In those with detrusor overactivity, especially with suprapubic SCI, the bladder wall can develop a lot of tone from the catheter rubbing against the bladder wall provoking uninhibited bladder contractions. The high tone in the bladder wall can in turn cause a functional obstruction at the ureteral orifices, resulting in decreased drainage from the upper tracts. Another result of the uninhibited contractions is autonomic dysreflexia. Therefore, periodic monitoring with urodynamics and the use of a pharmacological modality to quiet the bladder discussed in the section titled “Therapy for Incontinence Caused by the Bladder” should be strongly considered, particularly if there is urodynamic evidence of uninhibited bladder contractions, poor bladder wall compliance, and/or autonomic dysreflexia. Prophylactic antibiotics are not recommended for a patient with an indwelling catheter because of the risk of developing resistant organisms (106).

Before removing an indwelling Foley catheter, we believe it is best to obtain urine culture and sensitivity tests and to treat the patient with a culture-specific appropriate antibiotic. This is to decrease the risk of bacteremia if the patient is unable to void and develops a distended bladder. If a Foley catheter has been in place for 4 to 6 weeks before switching a patient over to IC, cystoscopy is recommended to remove eggshell calculi and debris that may have collected. Retrospective studies have reported that risks are higher with an indwelling Foley catheter compared with IC. These risks include the development of bladder stones; hematuria; bacteremia, especially if the catheter becomes obstructed; meatal erosions; penile scrotal fistulas; and epididymitis (128). However, it is important to note that in retrospective chart reviews, it is difficult to know if the indwelling catheter was put in place because of the complication or caused the complication. Prospective studies are lacking.

It has also been reported in retrospective studies that the risk of bladder cancer in those with SCI is increased in those

using IC compared with those who were not. The risk has been reported to occur after 10 years of an indwelling catheter (106). Although not necessarily the predominant histologic type of cancer, squamous cell carcinoma is more common in those with SCI using indwelling catheterization. However, it should also be noted that squamous cell cancer is rare, so even though there is a greater incidence in those with SCI, the number of individuals who develop squamous cell bladder cancer is actually low (109). In a recent study the age standardized incidence of bladder cancer in SCI patients was 30/100,000. This was the same incidence for the general population in the area where the study was conducted (129). It is recommended that those with indwelling catheters have more frequent cystoscopic examinations than those who do not have in an indwelling catheter (106). This is done primarily to evaluate and remove bladder stones; however any questionable areas of the bladder can be biopsied at the same time. We generally perform cystoscopy once a year in those with an indwelling catheter. This is done more frequently if a person has recurrent bladder stones.

### *Indwelling Suprapubic Catheterization*

If an indwelling catheter is going to be used as a long-term bladder management option, some men prefer to switch to a suprapubic catheter. Suprapubic catheters have a number of advantages to indwelling catheters because they pass directly into the bladder and not pass through the urethra. Some of the major advantages are that the catheter can be changed without undressing, the tubing is less likely to be sat on or kinked between a person's legs, for those with sensation, it is much more comfortable, it is less likely to interfere with sexual activity (especially men), and is much easier to clean around (especially woman). It is also considered completely reversible because once the suprapubic catheter is removed, the tract closes, usually within 1 to 2 days. A suprapubic catheter has been found to be safer than an indwelling Foley catheter because it decreases the risk of epididymitis, urethral stricture disease, and urethral irritation (128). It has been reported that with the exception for bladder stones, the results of suprapubic catheterization were comparable to paraplegic SCI patients managed with continuous IC. They concluded that suprapubic catheterization is a valuable option of urinary management for tetraplegic patients (130).

It has been recommended that suprapubic catheters be considered for individuals with (a) urethral abnormalities, such as stricture, false passages, bladder neck obstruction, or urethral fistula, (b) urethral discomfort, (c) recurrent urethral catheter obstruction, (d) difficulty with urethral catheter insertion, (e) perineal skin breakdown as a result of urine, (f) leakage secondary to urethral incompetence, (g) psychological considerations such as body image or personal preference, (h) a desire to improve sexual genital function, and/or (i) prostatitis, urethritis, or epididymo-orchitis (106).

A recent prospective study revealed that in those with an SCI, there is a gradual decline in renal function, no matter what type of bladder management is used. Those with indwelling catheters did better than those on IC (131). Another study

retrospectively evaluated 32 patients with SCI with an indwelling catheter and 25 with SCI without a catheter. There was a statistically higher incidence of bladder stones in those with indwelling catheters, but no overall statistically significant difference in upper-tract or lower-tract complications between the two groups. The authors suggested that the decision to manage a person with tetraplegia should not be based solely on the relative risks of complications of renal deterioration. Rather, the decision to avoid an indwelling catheter should reflect patient comfort, convenience, and quality of life (132).

The same principles of management for an indwelling urethral catheter apply to a suprapubic catheter with the exception that a 22 to 26 Fr catheter is used. The larger catheter has the advantage of being less likely to become kinked or get clogged.

### ***Reflex Voiding***

Another method of management that can be used in men with an intact sacral micturition reflex is reflex (spontaneous) voiding. This type of voiding involves having the person wear a condom catheter attached to a leg bag. The bladder has a spontaneous uninhibited contraction when it reaches a certain bladder volume. However, the volume that “triggers” the uninhibited bladder contraction is different for each person. One advantage to an external condom catheter and a leg bag is that it does not require good hand function. A caregiver can place on the condom catheter in the morning and not have to change it until the next day. Some assistance is needed, however, because even though the leg bag holds a 1,000 mL it should be emptied when it is half full. Similar to an indwelling catheter, another advantage is that there is no limit on fluid intake, in contrast to those who use IC as their method of bladder management. Major disadvantages are potential penile skin breakdown and having to wear an external condom catheter and leg bag and possibly a slightly increased risk of bladder infections compared with IC.

Because men who reflexly void usually have detrusor-sphincter dyssynergia, various treatments for the sphincter are often necessary. These include  $\alpha$ -blockers, urethral stents, botulinum toxin injections into the sphincter, and sphincterotomy (106). These options are discussed in more detail in the section titled “Urinary Retention due to the Sphincter.” Those with reflex voiding need to have their upper tracts and lower tracts monitored. Although there is agreement that elevated voiding pressures cause upper-tract problems, there is no consensus as to what voiding pressure will cause this damage (133–135).

One study revealed that the most important voiding parameter causing upper-tract stasis in those who reflexly void was the duration of the bladder contraction (136). Particularly before invasive treatment options, further studies are needed before treatment can be based solely on a numeric value of a specific urodynamic parameter. Currently, it is best to consider all of the variables and whether or not a person is having problems prior to making changes. Problems may include autonomic dysreflexia, recurrent bladder infections, vesicoureteral reflux,

kidney or bladder stones, kidney infection, or deterioration in bladder function (progressively higher postvoid residuals) or renal function (137).

### **Therapy for Incontinence Caused by the Sphincter**

Preexisting occasional urinary incontinence from a weak sphincter mechanism, commonly found in elderly females, may become worse following a loss of mobility. Those with sacral and cauda equina injuries may also have urinary incontinence due to the sphincter. However, those with lower motor injuries will frequently have enough intrinsic sphincter tone to prevent the occurrence of urinary incontinence unless the bladder becomes overdistended or there is increased abdominal pressure (during transfers).

Urinary incontinence due to the sphincter also occurs with suprasacral SCI in those who have had a urethral stent or sphincterotomy or have urethral damage from being overstretched by a long-term catheter or large-diameter urethral catheter. Care needs to be taken trying to increase the sphincter tone in a person with a suprasacral SCI because of exacerbation of detrusor sphincter.

Treatment for urinary incontinence due to the sphincter may be needed in those with SCI injuries if they have had prior treatment of their sphincter and want to switch to a different type of bladder management. An example would be a person who has had a sphincterotomy and wants to switch to IC or a suprapubic catheter.

### **Therapy for Incontinence Caused by the Outlet or Sphincter**

#### **Behavioral Treatment Options**

Timed voiding sometimes is helpful in patients with mild to moderate incontinence who have normal bladder function but an underactive urethral sphincter mechanism. The object is to have the patient void before the bladder reaches full capacity. At full capacity, intravesical pressure is more likely to overcome the urethral pressure, resulting in leakage.

Pelvic floor (i.e., Kegel) exercises also may be tried in neurologically intact patients with mild to moderate stress incontinence caused by the sphincter (138). There is a great variation in the number of sets and repetitions described by various authors, with the total number of exercise contractions varying from 8 to 160/d (139). Exercises sometimes are combined with commercial biofeedback units (140). Patients have to be highly motivated since effects may not be seen for 4 to 8 weeks.

#### **Pharmacologic Treatment Options**

Alpha-adrenergic agonists may be useful at improving minimal to moderate stress incontinence caused by the sphincter. Wyndaele has reported success at decreasing urinary leakage around the Foley catheter in incomplete SCI women with patulous urethras (98). Ephedrine and phenylpropanolamine were two commonly used agents. Ephedrine causes a release of norepinephrine as well as directly stimulating  $\alpha$ - and

$\beta$ -receptors. Phenylpropanolamine is pharmacologically similar to ephedrine but provides less CNS stimulation (141). Phenylpropanolamine is rarely used because of reports that it may result in an increase in the risk of hemorrhagic stroke, especially in women (142).

A 4- to 6-week course of estrogen supplementation may be helpful in postmenopausal women with atrophy of the urethral epithelium or irritative symptoms from atrophic urethritis (143). Its beneficial effect may result from improving the local mucosal seal effect or increasing sensitivity or improving the number of  $\alpha$ -adrenergic receptors (144). Potential side effects and contraindications need to be weighed against potential benefits of using any agents to treat incontinence caused by the sphincter (141).

Periurethral collagen injection therapy is FDA-approved for those with intrinsic urethral sphincter deficiency. Clinical trials have focused primarily on non-SCI individuals. In a review, silicone particles and carbon spheres gave improvement at 12 months equivalent to collagen. A comparison of paraurethral and transurethral methods of delivery of the bulking agent found similar outcome but with a higher rate of early complications in the paraurethral group. The review concludes that in women with extensive comorbidity precluding anaesthesia, injection therapy may represent a useful option for relief of symptoms for a 12-month period, although two or three injections are likely to be required to achieve a satisfactory result (145). Bulking agents may be useful in SCI individuals who have decreased sphincter tone.

Significant progress has been made using a person's own stem cells, which are injected into the urethra for those with weak urinary sphincters and stress urinary incontinence (SUI). It has been reported that at 1 year after implanting the cells, 94 of the 119 women (79%) were completely continent, 16 (13%) had a substantial improvement, and nine (8%) a slight improvement. Four patients were lost to follow-up. The incontinence and incontinence quality of life (I-QOL) scores, and the thickness, contractility, and EMG activity of the rhabdosphincter were significantly improved after treatment. The authors concluded that these results show the efficacy and safety of transferring autologous myoblasts and fibroblasts in the treatment of female SUI, after a follow-up of 1 year (146).

Before bulking agents or other treatment options are used, it is essential that detrusor overactivity or poor bladder compliance be ruled out with urodynamics and treated if present. Otherwise, increasing the urethral sphincter tone to prevent urinary incontinence may increase intravesical pressures, which may in turn result in back pressure and poor drainage from the upper tracts.

### Surgical Treatment Options

In patients with a selective injury affecting just the sphincter mechanism, such as postprostatectomy or pelvic fracture, surgical implantation of an artificial urethral sphincter should be considered. It has been recommended that surgery should be delayed at least 6 months to 1 year to make sure there is no

spontaneous return of sphincter function. Artificial sphincters are used infrequently in the adult SCI population, because they potentially can cause upper-tract damage in those with detrusor hyperreflexia and high intravesical pressure. In addition, there is an increased risk of prosthesis infection or erosion of the cuff in SCI patients because of frequent episodes of bacteriuria. Light and Scott (147) reported that 24% of their SCI patients developed infection requiring removal of the device.

For women with stress incontinence caused by the sphincter, or intrinsic sphincter damage, such as from a long-term indwelling catheter, a variety of surgeries have been developed to anatomically improve the urethral support and position. These procedures can be performed transabdominally, transvaginally, and even without surgical incisions. One- to three-year follow-up success rates have been reported to be 57% to 91% (148). A potential problem is that the operation works too well and causes retention. Patients therefore should be aware of the possibility of needing to perform postoperative IC. Other surgical options for those with intrinsic sphincter damage include surgical closure of the bladder neck followed by urinary diversion with an abdominal stoma that can be catheterized or the insertion of a suprapubic tube.

### Supportive Treatment Options

Supportive options are similar to those for incontinence caused by the bladder. Specifically, these include diapers, external condom catheters, and indwelling catheters.

### Therapy for Retention Caused by the Bladder Behavioral Treatment Options

Timed voiding combined with increasing intravesical pressure either manually (i.e., Crede maneuver) or through increased intra-abdominal pressure (i.e., Valsalva voiding) may allow bladder emptying in individuals with an underactive or areflexic detrusor. In patients with weak uninhibited bladder contractions, suprapubic bladder tapping may be used to trigger a contraction (149).

Crede refers to pushing down with a closed fist in the suprapubic area with enough force to express urine from the bladder. Valsalva refers to bearing down with intra-abdominal pressure with enough force to push urine out of the bladder. The SCI Consortium bladder management panel recommended that one should consider not using Credé and Valsalva as a primary method of bladder management in those with SCI. If these maneuvers are going to be used, it is best reserved for those who are unable to perform IC and have decreased urethral sphincter activity, such as elderly women or SCI men with lower motor lesions and sphincterotomy (106).

Credé and Valsalva maneuvers may cause exacerbation of hemorrhoids, rectal prolapse, or hernia. Increasing intra-abdominal pressure in those with sphincter-detrusor dyssynergia often worsens the dyssynergia (150). Vesicoureteral reflux is a contraindication to this type of voiding.

### Pharmacological Treatment Options

Bethanechol chloride, which provides relatively selective stimulation of the bladder and bowel and is resistant to rapid hydrolysis by acetylcholinesterase, is used to augment bladder contractions. A review of the literature shows that bethanechol is most useful in patients with bladder hypocontractility and coordinated sphincter function (151). Light and Scott (152) reported that it failed to induce bladder contractions in SCI patients with detrusor areflexia. Sporer et al. (153) found that bethanechol increased external sphincter pressures by 10 to 20 cm H<sub>2</sub>O in SCI men. Therefore, it should not be used in those with sphincter-detrusor dyssynergia. It also is contraindicated in patients with bladder outlet obstruction. Potential side effects and contraindications must be weighed against potential benefits when pharmacologic agents are used to improve emptying (154).

Two investigational agents to improve bladder emptying are prostaglandins and narcotic antagonists. Intravesical prostaglandin F<sub>2a</sub> was noted to increase detrusor pressures in SCI patients with suprasacral lesions (155). Narcotic antagonists are thought to block enkephalins, which are believed to inhibit the sacral micturition reflex (156).

### Surgical Treatment Options

There have been reports of surgically reducing the size of the bladder to decrease the postvoid residual; however, there is no effective way surgically to augment bladder contractions by operating on the bladder itself (157). Cloning and tissue engineering may be helpful in the future. Attempts at improving bladder emptying by performing a sphincterotomy in SCI men with urinary retention from detrusor areflexia have been reported. However, this is generally not recommended because there is a high failure rate at decreasing postvoid residuals if the bladder does not have contractions (158).

### Supportive Treatment Options

A successful method for management of failure to empty caused by the bladder in those with hand function is IC. In those who are unable to perform IC, an alternative is an indwelling urethral or suprapubic catheter. Principles of management have been previously discussed.

## Therapy for Retention Caused by the Outlet or Sphincter

### Behavioral Treatment Options

Timed voiding and biofeedback methods have not been reported as successful methods of treatment in patients with neurogenic sphincter-detrusor dyssynergia. Biofeedback has been reported to be successful in patients with voluntary pseudosphincter-detrusor dyssynergia. These patients, who often are children, voluntarily tighten their sphincters during voiding, resulting in large postvoid residuals and UTIs (161).

In SCI patients with neurogenic detrusor overactivity and detrusor-sphincter dyssynergia, anal stretching or scissoring and suprapubic bladder tapping have been reported

as approaches that temporarily interrupt the dyssynergia and allow voiding (162).

### Pharmacological Treatment Options

#### Alpha-Blocking Agents

In men with a suprasacral SCI and an intact sacral micturition reflex, reflex voiding into a condom catheter is sometimes used. However, upper-tract damage or elevated postvoid residuals can occur secondary to detrusor-sphincter dyssynergia. Alpha-adrenergic blocking agents have been shown to be effective at improving bladder emptying in patients with sphincter-detrusor dyssynergia and prostate outlet obstruction (163,164). In those with prostate outlet obstruction,  $\alpha$ -adrenergic blocking agents are effective because the prostate smooth muscle is mediated by  $\alpha$ -adrenergic stimulation. Placebo-controlled studies have shown both a clinically and statistically significant improvement in voiding in subjects taking phenoxybenzamine, prazosin, and more recently, terazosin (165).

Alpha-blocking agents may improve voiding in patients with sphincter dyssynergia secondary to an SCI due to several factors. After denervation, a supersensitivity of the urethra to  $\alpha$ -adrenergic stimulation can occur. In addition, there may be a conversion of the usual  $\beta$ -receptors to  $\alpha$ -receptors (24,26). Scott and Morrow (166) found that phenoxybenzamine worked well at decreasing residual urine volume in patients with suprasacral SCI and autonomic dysreflexia, but had variable effect on those without dysreflexia. An added benefit of  $\alpha$ -blockers is their ability to blunt autonomic dysreflexia (167). When deciding which  $\alpha$ -blocker to use, it is important to know that the manufacturer of phenoxybenzamine has indicated a dose-related incidence of gastrointestinal tumors in rats. There have been no cases of gastrointestinal tumors linked to phenoxybenzamine in humans in more than 30 years of use (168); however, the potential medicolegal issues of long-term use of phenoxybenzamine in young SCI patients should be considered.

The SCI Consortium bladder panel made several recommendations regarding  $\alpha$ -blockers in those with SCI. They recommend to consider avoiding  $\alpha$ -blockers in individuals who have symptomatic hypotension. They recommend that individuals are advised of the potential for complications of  $\alpha$ -blockers, such as orthostatic hypotension. In addition, when first starting on an  $\alpha$ -blocker, it is recommended to instruct the individual to take  $\alpha$ -blockers at night, when supine. These instructions are particularly important for individuals with high-level spinal cord injuries because of the potential for orthostatic hypotension. It was also recommended to use phosphodiesterase inhibitors with caution in individuals with a high-level SCI who are on  $\alpha$ -blockers. Particular caution should be used if  $\alpha$ -blockers and PDE5 inhibitors are prescribed together (106).

#### Other Oral Sphincter Relaxing Agents

Three drugs that have been used for striated external sphincter relaxation are baclofen, diazepam, and dantrolene. In our

experience, these agents are not as effective as  $\alpha$ -blocking agents and should not be used as the drugs of choice for external sphincter relaxation. However, the author has noted on urodynamic studies that when baclofen is being tapered in individuals with SCI, they have an increase in detrusor-sphincter dyssynergia. Baclofen functions as an agonist for the inhibitory neurotransmitter gamma-aminobutyric acid (GABA), which blocks excitatory synaptic transmission, resulting in external sphincter relaxation. Diazepam is believed to cause external sphincter relaxation by increasing GABA inhibitory transmission in the spinal cord. Dantrolene acts peripherally by decreasing calcium release from the sarcoplasmic reticulum, thereby inhibiting excitation-contraction of the striated skeletal muscle fibers (169).

### ***Botulinum Toxin***

Botulinum toxin injections into the sphincter mechanism have also been used as a treatment for detrusor-sphincter dyssynergia. When botulinum toxin is injected into the urethral sphincter or bladder wall, it inhibits acetylcholine release at the neuromuscular junction, which in turn blocks neuromuscular contraction and relaxes muscles that are either spastic or overactive. It can, therefore, relax sphincter spasticity in those with detrusor-sphincter dyssynergia. Because over time, reinnervation of the neuromuscular junction occurs, botulinum toxin frequently loses its effectiveness after 3 to 6 months. Therefore, reinjections usually are necessary. There is no limit to the number of reinjections that may be required. In one study, botulinum toxin was injected into 24 individuals with detrusor-sphincter dyssynergia, 21 had significantly reduced urethral pressures with a concomitant decrease in postvoid residual volumes (170).

Botulinum toxin injections to treat detrusor-sphincter dyssynergia are especially useful in SCI individuals who have symptomatic hypotension, have adverse effects to  $\alpha$ -blockers or difficulty with compliance at taking medications. The SCI Consortium bladder panel recommended to (a) consider the use of botulinum toxin injections into the sphincter to help improve voiding in individuals with SCI with detrusor-sphincter dyssynergia, (b) monitor and inform individuals after botulinum toxin injections that onset is delayed up to 1 week and that the drug may lose its effectiveness in 3 to 6 months (106).

They also recommended to consider avoiding the injection of botulinum toxin into the sphincter of SCI individuals who (a) have a neuromuscular disease, (b) have a known allergy to or previous adverse effect from botulinum toxin, (c) are currently on an aminoglycoside, (d) have insufficient hand skills or caregiver assistance, (e) are unable to maintain a condom catheter, and/or (f) are female (unable to wear an external condom catheter) (106).

As with all treatments, potential side effects and contraindications must be weighed against potential benefits when using pharmacologic agents to improve emptying (167,169).

## **Surgical Treatment Options**

### ***Urethral Stent***

Another method of sphincter dyssynergia treatment is the stainless steel woven mesh stent (e.g., Urolume Endourethral Wallstent, American Medical Systems), which holds the sphincter mechanism open. With an experienced team, this can be performed under local anesthesia. Because the sphincter is not cut, the procedure is potentially reversible with removal of the stent. The stent becomes covered by epithelium in 3 to 6 months, preventing calcium encrustations. A multicenter study of 153 men with SCI revealed a significant decrease in voiding pressures and postvoid residual urine volumes up to 2 years. Hydronephrosis resolved in 22 of 28 patients (78.6%). There was no loss of erectile function. Complications included mild postoperative hematuria in 10 patients (7.1%), penile edema in 2 patients, incrustation of the stent in 3 patients, stent removal (usually caused by stent migration) in 10 patients, and subsequent operation for bladder neck obstruction in 13 patients. Long-term follow-up studies are under way. This device has recently been approved by the FDA for the treatment of urethral strictures (171). In a 12-year follow-up study, five of the seven SCI men with urethral stents developed bladder neck dyssynergia of varying degrees, as shown on VCMG; all were successfully treated with bladder neck incision. There were no problems with stent migration, urethral erosion, erectile dysfunction, or autonomic dysreflexia (172).

The SCI Consortium bladder panel recommended to consider avoiding a urethral stent in SCI individuals who (a) have insufficient hand skills or caregiver, (b) assistance to manage a condom catheter, (c) are unable to maintain a condom catheter, (d) are female, and (e) have urethral abnormalities (106). They are also advised that the individual be told of the potential for complications of urethral stents, such as (a) stone encrustation, (b) stent migration, (c) persistence of autonomic dysreflexia, (d) possible need for removal or replacement, (e) difficulty with removal, (f) possible urethral stricture after removal of stent, (g) urethral trauma, (h) tissue growth into the stent blocking urine flow, and (i) urethral pain (106).

### ***Transurethral Sphincterotomy***

Transurethral sphincterotomy (TURS) is a well-established treatment for SCI men with sphincter-detrusor dyssynergia. Indications include vesicoureteral reflux, high residuals with severe autonomic dysreflexia or recurrent UTIs, upper-tract changes with sustained high intravesical pressures, and poor compliance or side effects from medications being used to relax the outlet. Perkash reported a more than 90% success rate at relief of dysreflexic symptoms, decrease in residual urine, decrease in infected urine, and significant radiologic improvement. He stressed the importance of extending the incision to the bladder neck (173). The SCI Consortium Bladder panel recommended that one should consider TURS to treat detrusor-sphincter dyssynergia in males with SCI who want to use reflex voiding and who (a) have insufficient hand skills or caregiver assistance to perform IC, (b) have a repeated history

of autonomic dysreflexia with a noncompliant bladder, (c) experience difficult catheterization due to false passages in the urethra or secondary bladder neck obstruction, (d) have inadequate bladder drainage with severe bladder wall changes, (e) drop in renal function, (f) vesicoureteral reflex and/or (g) stone disease, (h) have prostate-ejaculatory reflux with the potential for repeated epididymo-orchitis, (i) experience failure with or intolerance to anticholinergic medications for IC, and/or (j) experience failure with or intolerance to  $\alpha$ -blockers with reflex voiding (106).

It was recommended to consider avoiding TURS in males with a small retractable penis unable to hold an external collecting device unless a penile implant is planned following TURS.

The SCI Consortium Bladder panel recommended to advise males with SCI of the potential for complications of a sphincterotomy, such as (a) significant intraoperative and perioperative bleeding, (b) clot retention, (c) prolonged drainage with a large diameter catheter, (d) urethral stricture, (e) erectile dysfunction, (f) ejaculatory dysfunction, and/or (g) reoperation in 30% to 60% of cases.

The major concerns of most SCI patients are that the procedure is irreversible, it is a surgical procedure, and they will have to wear a leg bag. The traditional electrocautery method of performing a sphincterotomy has been reported to be at times causing bleeding requiring blood transfusion varying from 5% to 26%. This risk of bleeding has been largely eliminated with the use of Nd:YAG contact laser sphincterotomy (106).

Longitudinal studies have shown a 30% to 60% sphincterotomy failure rate. This has been attributed to a variety of causes, such as poor patient selection (i.e., those with detrusor areflexia or bladder contractions  $<30$  cm H<sub>2</sub>O), recurrent detrusor-sphincter dyssynergia, failure to recognize the need for a concomitant procedure (such as bladder neck incision or prostate resection), or new-onset detrusor hypocontractility (174).

### Supportive Treatment Options

Supportive treatment options for the outlet are the same as those for retention caused by the bladder—specifically, IC or indwelling catheters. Occasionally, a person has so much sphincter spasticity that it is difficult to pass a catheter. Instillation of lidocaine jelly down the urethra 5 minutes before catheterization, administration of  $\alpha$ -adren-ergic blockers, or use of a coudé catheter often facilitates catheterization.

### Pediatric Bladder Management Considerations

Children with incomplete emptying and sphincter dyssynergia caused by a nonneurogenic learned disorder have been treated successfully with biofeedback. This has involved looking at or listening to their sphincter EMG patterns during voiding. Sugar and Firlit (175) reported that all ten of their patients aged 6 to 16 years converted to a synergistic voiding pattern within 48 hours of therapy.

The same pharmacologic principles discussed under the general management section apply for children. The age of the child and decreased dosages need to be considered.

The same surgical procedures discussed under management can be used in children. In the past, children with vesicoureteral reflux were treated with urinary diversion, but because of long-term complications of urinary diversion and the excellent success of IC and ureteral reimplantation, this rarely, if ever, is used today. Surgical procedures for children with severe incontinence include an anterior fascial sling around the urethra and artificial urinary sphincter. There have been reports of 90% long-term success rates with the use of the artificial sphincter in children (176).

Clean IC has been shown to be effective treatment for children with failure to empty. In those with incontinence caused by the bladder, an anticholinergic medication often is also required (oxybutynin, 1.0 mg/yr of age twice daily). Parents often can learn IC in 1 day. It is thought that parents and children adjust to this program if it is started when the child is a newborn. There have been no reported cases of urethral injury, epididymitis, or UTIs requiring hospitalizations caused by this procedure. Children usually can begin performing their own IC at age 5 years. A child's bladder capacity can be calculated using the formula: bladder capacity = 2 + (age) (in ounces).

In those who are unable to have a successful IC program due to problems such as significant urinary incontinence due to poor sphincter tone, small bladder capacity, or difficulty catheterizing the urethra, an alternative is to create a continent urinary diversion with either the Mitrofanoff principle (appendicovesicostomy) or a Monti tube (ileovesicostomy) can be performed. A concomitant bladder augmentation and urethral sling is frequently needed. In one 10-year follow up study, 95% (51/54) of patients were continent, 90% (36/40) reported satisfaction, and 10% (4/40) reported dissatisfaction. Complications included bladder calculi (15%; 8/54), stomal stenosis (9%; 5/54), stomal bleeding (5%; 3/54), small bowel obstruction (2%; 1/54), and superficial wound dehiscence (2%; 1/54). This 10-year experience underscores that while complications do occur, there is successful long-term outcomes and durability of continent urinary diversions in children with neurogenic bladders (177).

## COMPLICATIONS OF VOIDING DYSFUNCTIONS

### Urinary Tract Infections

#### Definition of a Urinary Tract Infection

There is confusion in the literature and health care professionals regarding the definition of a true bladder UTI versus bacterial colonization in a person with a neurogenic bladder. It is important that a person being treated has a true UTI. Those being treated who do not have a true UTI will likely have unnecessary urine cultures, risk side effects of

antibiotics, and potentially develop resistant organisms, which will be difficult to treat if they develop a true UTI. In children and young able-bodied individuals, bacteria in the urine usually signify a bladder infection. However, no matter what type of bladder management, bacteriuria is common and usually represents colonization, not a bladder infection. The literature sometimes calls this an asymptomatic UTI. It is important to point out to patients and families that when an article says that a person will develop a bladder infection within a few days of putting in a catheter, or performing IC the article is referring to colonization not a true bladder infection. To help clarify this misunderstanding, the National Institute on Disabilities and Rehabilitation Research had a consensus conference on UTIs in those with SCI. They came up with a very useful definition to help clarify the difference between a true UTI and bacterial colonization. To have a true UTI an individual with an SCI should meet three criteria. These are (a) the presence of bacteria in the urine, (b) an increase in white blood cells in the urine (pyuria) and (c) the onset of new symptoms (178). The following will give a further discussion and definition of each of these criteria.

### Bacteriuria

Traditionally, a UTI was defined as more than 100,000 organisms in a midstream urine sample (179). However, studies show that symptomatic patients often have fewer than 100,000 organisms per milliliter. It has been found that 30% of able-bodied women with acute dysuria had less than 10,000 coliforms per milliliter, and many had less than 200/mL (180,181).

Bacteriuria is a common finding in patients with voiding dysfunctions. Lloyd et al. followed 181 new SCI patients discharged from an acute SCI center initially with sterile urine and on a variety of bladder management programs for 1 year. At 1 year, 66.7% to 100% had at least one episode of bacteriuria, depending on their bladder management program (182). Maynard and Diokno (183) reported on 50 new SCI inpatients on IC and found that 88% had one or more episodes of bacteriuria (i.e., any bacteria present). Elderly patients often compose a large part of the patient population in a rehabilitation hospital. Asymptomatic bacteriuria has been found to be present in 10% to 25% of community-dwelling and 25% to 40% of nursing home patients older than 65 years of age (184).

In SCI patients, Rhame and Perlash (185) reported that any specimen with more than 1,000 coliforms per milliliter was significant. Donovan et al. (186) thought that the appearance of any count of the same organism for two consecutive days was significant. The National Institute on Disability and Rehabilitation Research UTI consensus conference based the definition of significant bacteria on the method of urine collection and colony count. Significant bacteria did not necessarily mean an infection but, rather, confidence that the bacteria cultured were from the bladder and not contamination. For those on IC, "significant" meant greater than  $10^2$  colony-forming

units (cfu)/mL; for those who did not use catheterization, greater than  $10^4$  cfu/mL; and for those who used an indwelling catheter, any detectable pathogens (178).

### Pyuria

Elevated white blood cells in the urine (pyuria) generally signifies tissue invasion. Therefore, this is a reasonable reliable sign that a person has a UTI, particularly if he or she does not have a neurogenic bladder. Stamm et al. (181) found that 96% of able-bodied patients with symptomatic infections had greater than 10 leukocytes/mm<sup>3</sup>. Deresinski and Perlash (187) reported that 79% of 70 SCI patients with symptoms and bacteriuria also had pyuria; however, 46% of asymptomatic patients also had significant pyuria. A person with a neurogenic bladder may have elevated WBCs but may not have a symptomatic "true" bladder infection. Possible causes include irritation from an indwelling catheter rubbing against the bladder wall, an intermittent catheter passing up the urethra, a bladder stone, or upper-tract problem such as a kidney stone. Anderson and Hsieh-ma (188) found that Gram-negative bacteria caused significant pyuria, but that this was not true of *Staphylococcus epidermidis* or *Streptococcus faecalis*, even in high numbers. Therefore, in cases of Gram-positive bacteria and a new onset of symptoms but no significant pyuria, a bladder infection should be considered.

### Sign and Symptoms

The third component in the definition of a UTI is the new onset of signs and symptoms. It is important to emphasize the "new onset" to patients when asking about symptoms since many have chronic symptoms such as spasticity or pain. Signs and symptoms of a UTI involving the lower tract result from tissue invasion of the bladder wall with accompanying inflammation and generation of leukocytes from the bladder mucosal. In general, these may include cloudy urine, dysuria, frequency, urinary incontinence, or hematuria. Unless a person has had acute retention or urologic instrumentation, which can cause a bacteremia, it is very unlikely that a significant fever is due to a bladder infection. If a person complains of a high fever, a kidney infection (pyelonephritis) or nonurinary cause (such as an infected pressure ulcer) should be considered. Because many SCI patients have decreased or no bladder sensation, they may present with less specific signs and symptoms, such as weakness or malaise, increased abdominal or lower-extremity spasticity, new onset of urinary incontinence, occasionally retention from increased sphincter-detrusor dyssynergia, or autonomic dysreflexia in those with a lesion above T6.

Patients with acute upper-tract involvement may present with any of the above signs and symptoms. They also usually will have fever and chills and an elevated serum white blood cell count. Those with sensation usually report costal vertebral angle tenderness. It should be noted in the elderly that signs and symptoms may be much more subtle and patients may present simply with confusion or lethargy. UTIs also should be considered in the differential diagnosis of new cognitive changes in a head-injured patient.

### Treatment of Asymptomatic Urinary Tract Infections

Guidelines for treatment have been difficult to establish for asymptomatic bacteriuria (colonization) because of articles that combine symptomatic UTIs and asymptomatic UTIs together and controversy whether or not colonization itself is a risk factor for UTIs and upper-tract damage. Ideally, the urine should be sterile; however, the side effects of antibiotics and development of resistant organisms need to be taken into account. Kass et al. followed 225 children on IC for 10 years and reported that in the absence of vesicoureteral reflux, bacteriuria proved innocuous, with only 2.6% of subjects developing fresh renal damage. In high-grade reflux, however, 60% developed pyelonephritis (189).

Lewis et al. studied 52 acute SCI patients during their initial hospitalization. Seventy-eight percent of patients had greater than 100,000 organisms, but only 13% had symptoms and required antimicrobial therapy over 6 months. Of interest is that 35% of cultures changed weekly from positive to negative, negative to positive, or one organism to another, necessitating a short course of antibiotics (190).

An accurate characterization of voiding dysfunction—such as voiding pressure, bladder compliance, and postvoid residuals, along with accurate characterization of level and completeness of injury—often is lacking in various studies discussing UTIs in SCI patients. Currently, there is a general consensus not to treat asymptomatic bacteria in those with neurogenic bladders. There is a strong consensus that asymptomatic bacteriuria in a patient with an indwelling Foley catheter should not be treated. Attempts should be made to eradicate asymptomatic bacteriuria before urologic instrumentation, in hydronephrosis particularly if this is due to partial obstruction since further obstruction could lead to sepsis, or in the presence of urea-splitting organisms. The authors have noted that some individuals are colonized with urea-splitting organisms such as *Proteus*. The authors will do a careful evaluation of the upper-tract (CT scan) and lower-tract cystoscopy and give two or three courses of antibiotics. If the organism persists, the author does not continue to treat the organism and monitors for possible stone formation 6 months to 1 year later. Use of prophylactic antibiotics is sometimes used for high-grade reflux. This should be strongly considered if individuals are getting episodes of pyelonephritis. However, it is best to control the reflux by preventing bladder overdistention, reducing intravesical pressure and/or change in bladder management (such as switching to an indwelling catheter).

### Treatment of Symptomatic Urinary Tract Infections

Once a urine culture has been obtained, empiric oral antibiotic treatment can be started for patients with minimal symptoms while waiting for the culture results. Patients usually do well with a 7-day course of antibiotics. In those with high fevers (signifying pyelonephritis), dehydration, or autonomic dysreflexia, more aggressive therapy and upper-tract evaluation should be instituted. It is our opinion that these patients should be hospitalized, closely monitored, hydrated, and given broad-spectrum antibiotics (e.g., gentamicin and ampicillin)

while waiting for the culture results and for defervescence of the fever. It is important to have an indwelling Foley catheter in place during intravenous or oral fluid hydration to keep the bladder decompressed. We believe that it also is beneficial to give an anticholinergic medication while the Foley catheter is in place; this will decrease the intrinsic pressure within the detrusor, allowing relaxation of the ureterovesical junction and improving drainage of the kidneys. Tempkin et al. (191) showed on renal scans that there was improved drainage of the upper tracts in SCI patients given anticholinergics. Anticholinergic medications will also help prevent autonomic dysreflexia in those with injuries at T6 and above. Autonomic dysreflexia may occur from uninhibited bladder contractions that may be provoked by the indwelling catheter. Patients with significant fever are likely to have upper-tract involvement (i.e., pyelonephritis) and, therefore, be continued on antibiotics longer than patients with bladder infections.

In addition, these patients with high fevers should undergo a urologic evaluation for cause of urosepsis. Acutely, this should consist of a plain abdominal radiograph to rule out an obvious stone, followed by a renal ultrasound. If there is a question of a stone, hydronephrosis, or persistent fever, a CT scan will be helpful to further define the anatomy. Once the patient has been treated, it is often necessary that he or she undergoes a cystogram to evaluate for reflux, a cystoscopy to evaluate the bladder outlet and bladder, and urodynamics to evaluate voiding function.

### Complications of Urinary Tract Infections

In addition to acute lower UTIs (i.e., cystitis) and acute upper UTIs (i.e., pyelonephritis), the physician should be aware of other potential problems. Those from lower UTIs include epididymitis, prostatic or scrotal abscess, sepsis, or an ascending infection to the upper tracts. Complications that may occur from upper-tract infections include chronic pyelonephritis, renal scarring, progressive renal deterioration, renal calculi if there is a urea-splitting organism such as *Proteus*, papillary necrosis, renal or retroperitoneal abscess, or bacteremia and sepsis.

### Role of Prophylactic Antibiotics

There is controversy over the usefulness of prophylactic antibiotics. Anderson (192) reported a statistically significant difference in bacteriuria in SCI inpatients on a combination of oral nitrofurantoin and neomycin/polymyxin B solution compared with controls. Merritt et al. (193) reported a statistically significant decrease in bacteriuria with methenamine salt or co-trimoxazole compared with controls at 3 to 9 months, but not at greater than 15 months. Maynard and Diokno (183) reported that antibiotic prophylaxis significantly reduces the probability of a laboratory infection but not the probability of a clinical infection. Kuhlmeier et al. (194) evaluated vitamin C and a number of antimicrobial agents as prophylactic agents and found no beneficial effect in SCI patients compared with controls. These studies seem to show that prophylactic agents do not have a long-term effect in decreasing bacteriuria

compared with controls. The role of prophylactic antibiotics in patients with recurrent clinical infections, anatomic abnormalities such as vesicoureteral reflux, or hydronephrosis is not known. A major concern using prophylactic antibiotics is the development of resistant organisms.

### Bladder Stones

Bladder calculi are the second most common cause of morbidity (following UTIs) in those with SCI (195). The reason for this is the common use of indwelling catheters following SCI and the close association of bladder stones and indwelling catheters (196–198). The 1995 National SCI database found that in women, indwelling catheters are the second most common type of management at discharge (35%) and most common type of management in those at 5 and 10 years out from injury (46.5% and 55.1%, respectively). In men at discharge, indwelling catheters were the third most common type of bladder management (20.5%) and second most common type of management at 5 and 10 years out from injury (27.1% and 36.4%, respectively) (195).

A prospective study had a 35% incidence of bladder stones in those with indwelling catheters (197). In another large retrospective study of 500 patients, the absolute annual risk of stone formation in patients with a catheter was 4% compared with 0.2% for those on intermittent self-catheterization. However, having formed a stone, the risk of forming a subsequent stone quadrupled to 16% per year. Bladder stones were no more likely to form in patients with suprapubic catheters compared to those with indwelling urethral catheter type (198). We have noted that if a person has bladder stones, they are likely to have a recurrent stone. Conversely, those who do not have a stone are less likely to have a bladder stone on a subsequent cystoscopic examination.

The majority of bladder stones are composed of struvite caused by a urease-producing organism. These organisms lay down a biofilm on the surface of the catheter that then forms into stones. Complications from indwelling catheters include recurrent UTIs, hematuria, and blockage of an indwelling catheter with potential life-threatening autonomic dysreflexia (195,197). Prevention of stones is best accomplished by catheter changes every 2 to 4 weeks, and treatment of stone-forming organisms such as *Proteus*. In those with frequent recurrent bladder stones, daily instillations of renacidin (citric acid, glucono-delta-lactone, and magnesium carbonate) irrigation (15 to 30 mL left in the bladder for 5 to 10 minutes, two to three times a day) may be tried. Instillations may cause a problem in those with reflux or they may cause autonomic dysreflexia with bladder distention. In individuals identified as frequent stone formers, weekly catheter changes have also been found to reduce bladder stones (199). We have noted that weekly catheter changes also decrease catheter blockage in those with recurrent bladder stones.

The role of high fluid intake at preventing bladder stones is not known. The standard treatment of bladder stones involves cystoscopy and the breaking up and removal of the stones under direct visualization. Unfortunately, abdominal

x-ray is not a reliable method to detect bladder stones in individuals with SCI. Only 21% of bladder stones found during cystoscopy were detected by the x-ray (200). Individuals with stones on their catheter should, therefore, be referred for cystoscopy to prevent catheter clogging. Finding encrustation of the catheter when it is removed is a reliable sign that there are retained stones in the bladder. Eighty-six percent of those with catheter encrustation were found to have stones on cystoscopy (197).

### Bladder Cancer

Individuals with SCI who have indwelling catheters or bladder augmentations have been reported to have a higher risk for bladder cancer than their able-bodied counterparts (201,202). Among those with indwelling catheters, this increased risk may only be for squamous cell cancer, which is an extremely rare form of bladder cancer (129) (see above discussion of bladder cancer in the section “Indwelling Urethral Catheterization”). Possible causes include chronic irritation from UTIs, stasis of urine, bladder stones, or exposure of the bowel mucosal to urine following a bladder augmentation or urinary diversion (201,202). There have been a few reports of adenocarcinoma of the bladder in patients who have had an augmentation cystoplasty for more than 10 years (110). Hematuria was frequently a presenting sign in those with bladder cancer (202). These studies suggest that an evaluation of hematuria is important, particularly in the absence of a UTI, and yearly cystoscopy should be performed in people who have had indwelling catheters for more than 10 years. Before 10 years, many centers perform yearly cystoscopy on those with an indwelling catheter, primarily to rule out bladder stones. The role of other screening methods, such as cell cytology, is under investigation.

### Vesicoureteral Reflux

Price and Kortke (203) reported in an 8-year study that vesicoureteral reflux was one of the factors frequently associated with renal deterioration after SCI. Fellows and Silver (204) found that there was a definite association between the degree of reflux and renal damage. Vesicoureteral reflux in children has been associated with a congenital shortening or absence of the submucosal ureter, absence of ureteral muscle in the submucosal segment, or a paraureteral diverticulum of the bladder (205). In people with neurogenic voiding dysfunctions, high intravesical pressures are thought to be a major cause of reflux. Recurrent cystitis and anatomic changes in the oblique course of the intravesical ureter caused by bladder thickening and trabeculation are believed to be other causes of reflux. Renal deterioration from reflux is thought to be secondary to recurrent pyelonephritis, resulting in renal scars as well as back-pressure hydronephrosis.

The mainstay of treatment in those with reflux and voiding dysfunction is to lower intravesical pressures and eradicate infections. Ureteral reimplants are technically difficult to perform in a trabeculated bladder and have not been uniformly successful.

## Renal Calculi

Approximately 8% of patients with SCI develop renal calculi (i.e., staghorn calculi or struvite stones) (206). Kuhlemeier et al. (207) found that renal calculi were the single most important cause of renal deterioration. Without treatment, a patient with a staghorn calculus has a 50% chance of losing the involved kidney (208). DeVivo and Fine (206) evaluated 25 SCI patients who developed calculi and 100 SCI patients who did not have calculi and found that those with calculi were more likely to have neurologically complete quadriplegia, have *Klebsiella* or *Serratia* infections, prior history of bladder calculi, and high serum calcium values. Patients who present with persistent *Proteus* infections also should be monitored for renal calculi. Urea-splitting organisms form alkaline urine that in turn causes supersaturation and crystallization of magnesium ammonium phosphate.

Previously, a surgical pyelolithotomy or nephrolithotomy was performed to remove these stones (Fig. 51-7). Newer techniques, including percutaneous nephrolithotomy and extracorporeal shock wave lithotripsy, have largely replaced open surgical procedures (209). All of these procedures need to be combined with sterilization of the urinary tract of urea-splitting organisms. DeVivo and Fine (206) reported a 72% recurrence rate within 2 years of the first kidney stone. Investigations are under way on the use of acetohydroxamic acid as a prophylactic

**FIGURE 51-7.** Example of a surgically removed staghorn calculus. This calculus completely filled the renal pelvis and calyces and assumed their shape.

agent; limitations of this agent are reported side effects and high cost (210).

## Hydronephrosis

Ureteral dilation for any reason results in inefficient propulsion of the urine bolus caused by inability of the walls to coapt completely, as well as in decreased intraluminal pressure caused by the increased ureteral diameter. Over time, this may result in further distention of the ureter with eventual hydronephrosis (7,211). There are several causes for ureteral dilation. It can occur transiently from a brisk diuresis effectively overloading the ureters, not allowing enough time for individual boluses to travel down the ureter. Another cause may be a mechanical obstruction, such as a stone or stricture. Those with poor bladder wall compliance, sphincter-detrusor dyssynergia, or outlet obstruction may develop a functional obstruction caused by high intravesical pressures. The elevated intravesical pressure increases the tension within the bladder wall, which in turn constricts the submucosal ureter, increasing the hydrostatic force within the bladder. Ureteral dilation will occur if ureteral peristalsis is unable to overcome these increased pressures (212).

McGuire et al. (91) reported that 81% of myelodysplastic children with leak point pressures greater than 40 cm H<sub>2</sub>O developed upper urinary tract changes, whereas only 11% with leak point pressures below 40 cm H<sub>2</sub>O developed upper-tract changes. Hydrostatic forces in the ureter and kidneys also may be increased by vesicoureteral reflux blocking the downward egress of urine (212). Teague and Boyarsky have identified another potential cause of ureteral dilation. They found that *Citrobacter* sp. and *Escherichia coli* from human urine cultures injected into the lumen of dog ureters produced marked suppression of peristalsis and ureteral dilation lasting up to 2 hours (213).

## Renal Deterioration

Renal failure previously was the leading cause of death following SCI. The death rate from renal causes was reported in the 1960s at between 37% and 76%. Careful monitoring of the upper and lower urinary tract combined with effective bladder management programs has markedly reduced the incidence of renal failure. Price and Kottke (203) followed 280 patients for 8 years and reported 78% had good function, 13% mild deterioration, 4% moderate deterioration, and 5% severe deterioration. Factors most frequently associated with renal deterioration were vesicoureteral reflux, renal calculi, recurrent pyelonephritis, and recurrent decubitus ulcers. Kuhlemeier et al. evaluated 519 SCI patients with renal scans for up to 10 years. They found that factors associated with a statistically significant decreased ERPF were tetraplegia, renal stones, female patients older than 30 years of age, and a history of chills and fever presumably caused by acute UTIs. Renal calculi were the most important cause. Factors not found to be statistically significant included years since injury, presence of severe decubitus, bladder calculi, bacteriuria without reflux, and completeness of injury (207).

### Renal Amyloidosis

Amyloidosis has rarely been reported in those with SCI. Of particular concern in those with SCI has been renal involvement (214–218). The clinical findings vary with the organ involved. If the liver and spleen are involved, these organs will usually be palpable. If the kidneys are involved, albuminuria has been reported as a consistent sign. Edema of hypoproteinaemia, hyaline and granular casts, and azotemia are late findings of renal involvement (215). It has been hypothesized that amyloidosis is due to the triad of three inflammatory processes, specifically pyelonephritis, decubiti, and osteomyelitis. It has been suggested that amyloidosis is associated with the total mass of the inflammation rather than a single focus (214).

It is interesting to note that most of the publications are from 30 or more years ago. Improved methods to treat pyelonephritis, pressure ulcers, and osteomyelitis have probably contributed to this being a very infrequent occurrence in a person with SCI. There is some controversy on the reversibility of amyloidosis. It has been reported that after the treatment of pressure sores with skin grafts, serum albumin improved and patients clinically felt better (216). It has also been found that albumin improved and there was remission of the nephritic syndrome. Renal biopsies did not show any decrease in amyloid (217). Another study reported that amyloid did regress after treatment of the inflammatory condition (218). These studies help to emphasize the importance of attempting to prevent and to effectively treat secondary inflammatory conditions in those with SCI.

### Autonomic Dysreflexia

Another potential problem that can occur in those with injuries at thoracic level 6 (T6) and above from urologic causes is autonomic dysreflexia. Of most concern is a sudden severe elevation in blood pressure that occurs until the cause of the autonomic dysreflexia is removed. Other symptoms may include sweating, flushing, “goose bumps,” headache, and bradycardia (219). “Silent” dysreflexia may also occur, in which there are no symptoms of dysreflexia despite a significant rise in blood pressure (89).

Because autonomic dysreflexia can occur with any noxious stimuli, various urologic problems, such as bladder distention, UTIs, epididymitis, and urologic instrumentation, may provoke its onset. The ejaculation reflex, whether it is induced by vibratory stimulation or electroejaculation, will usually cause autonomic dysreflexia in those with injuries at or above T6 (219). The onset of uninhibited bladder contractions has been noted on urodynamics studies frequently to cause a rise in the blood pressure (89).

When a person presents with autonomic dysreflexia, one should first sit the person up and loosen any restrictive clothing. It is then important to evaluate for any potential urologic causes, such as a blocked catheter or kinked catheter tubing. If a catheter is blocked and going to be changed, and lidocaine jelly is readily available, consideration should be given to instilling the lidocaine into the urethra before the catheter change. This helps to decrease sensory afferent input that

could increase autonomic dysreflexia. A national guideline on the acute management of autonomic dysreflexia for individuals with SCI presenting to health care facilities has been published (219). Lidocaine can also be instilled into the bladder before urologic procedures or during an acute episode of autonomic dysreflexia when a person is felt to be having a UTI (97).

## THE GASTROINTESTINAL SYSTEM

Traditionally, urinary and gastrointestinal system impairments are grouped together for discussion because of similarities in anatomic location, function, and neurologic innervation. However, there are limits to further extension of this analogy and a few important distinctions. The colon is only the terminal segment of the gastrointestinal tract and is greatly influenced by activity up the alimental pathway. Neurogenic bowel refers primarily to functional changes in the colon and pelvic floor, although a variety of neurologic conditions affect various other gastrointestinal organs as well (220). The sequelae of neurogenic bladder dysfunction can frequently be life threatening, whereas neurogenic bowel dysfunction is seldom life threatening but certainly life limiting, affecting the quality of life. Neurogenic bowel dysfunction can prevent willful continence, voluntary defecation, and self-management of cleanup; cause dread and fear of incontinence; and constrict full participation in life (221).

SCI is the condition that is most frequently associated with neurogenic bowel dysfunction, although there are many other neurologic conditions contributing to gastrointestinal dysfunction as well. Furthermore, gastrointestinal involvement is not limited to the colon after SCI; all segments are affected (220). Oral hygiene is affected in patients with high tetraplegia. SCI can contribute to dysphagia as a result of local protrusion of osteophytes discs or cervical fixation hardware. Gastric ulcers are more common after SCI and peak during the first few weeks after injury. The prevalence of gallstones after SCI can reach 30%, yet in spite of this high prevalence, acute cholecystitis does not occur with greater frequency or at increased risk for mortality (222,223). The transverse portion of the duodenum (third portion) crosses the midline within an angle created between the aorta posteriorly and the superior mesenteric artery, which arises off the anterior wall of the aorta superior to the transverse duodenum. Rapid weight loss causes loss of the fat pad that maintains this angle and may result in constriction of the third portion of the duodenum. Superior mesenteric artery syndrome produces gastric distention, bloating, and vomiting and further weight loss that results from the superior mesenteric artery descending and pinching off the distal duodenum; this is termed the *nutcracker effect*. Dilation of the stomach and the proximal duodenum are present radiographically.

While infrequent, nontraumatic pancreatitis sometimes occurs after acute SCI, this may be due to sphincter of Oddi spasm, thickening of pancreatic secretions, and vagal dominant innervation (220,224). Serum amylase, though nonspecific, is

the most useful tool to prompt further studies and initiation of supportive care (NPO, hydration and optimization of oxygenation). Unfortunately, stool guaiac is so nonspecific as to be irrelevant in diagnosis of pancreatitis, and hypocalcemia (speculated to be the consequence of ionized extracellular calcium becoming linked to fats in the peripancreatic inflammatory phlegmon also known as saponification) is a late finding in very severe pancreatitis—not a useful diagnostic tool either.

## Anatomic and Physiological Considerations

### Colon

The large intestine serves to desiccate and form fecal matter as it is transported from the ileum to the rectum. There the feces can be willfully evacuated at the right time and place. In addition to its role as a transport and storage organ, the colon functions to absorb water and electrolytes. The colon normally reduces the approximately 1,500 mL of small intestinal content that is introduced into the cecum to about 150 mL/d.

Colonic propulsion of the fecal contents requires motility, a term frequently misused and often misunderstood. Unfortunately, a variety of experimental measurements have been associated with motility and attributed to functional fecal transport (225). Motility and fecal transport are measured differently. For motility, colonic wall contractions can be quantified manometrically (226,227), and/or electronically via electrode recordings of the patterns and intensity of smooth muscle activation (228). It is not possible to deduce the movement of material through the colon by the measurement of electrical activity, however. Therefore, unqualified terms such as *increased motility* or *decreased motility* say little about success with fecal transport. Alterations in colonic transport may be caused by events that occur outside of the colon, such as distal obstruction or proximal dilation mediated by the intestinal colic inhibitory reflex. Indices of motility may be abnormal in situations with low transport. Therefore, interventions directed solely at correcting the abnormal indices of colonic motility may not be effective.

The most clinically useful index of overall colonic function is colonic transit time, the amount of time required for contents to pass from the cecum to the outside. Several techniques exist for measuring transit time. A practical economic method uses radio-opaque markers that are swallowed and followed through the intestinal tract with serial abdominal radiographs (229,230). Swallowed markers are counted on serial radiographs (229). Although even such objective measures have limitations, as expected, the transit of material through the colon does depend on colonic motility. After SCI, in the absence of regular spontaneous or willful defecation, transit and motility are dependent on regular scheduled bowel care. Rectal distention in itself can reflexively inhibit peristalsis and affect alimentary function as proximal as the stomach, preventing gastric emptying.

### Anorectum

The anal canal provides the primary mechanism for fecal continence and is the barrier that must be traversed for evacuation

to occur. The *internal anal sphincter* (IAS) is the specialized thickening of the circular smooth muscle layer of the rectum that maintains a continuous state of maximal contraction. It is responsible for the majority of resting tone in the anal canal (231).

Normal internal anal canal resting pressures range from 50 to 100 cm H<sub>2</sub>O. This resting tone is not altered after SCI (232). The *external anal sphincter* (EAS) is a striated muscle that is continuous with the pelvic floor and is innervated by the pudendal nerves bilaterally. The EAS, along with muscles of the pelvic floor, displays the unusual property of continuous electrical activity in both the waking and sleeping states (233). Presumably, this special property allows the EAS and pelvic floor to maintain continence without conscious will and during sleep. Although the EAS plays a small role in the resting state, contraction of the EAS can double anal canal pressure for short periods of time. External sphincter function is felt to be important during events that are an acute threat to continence, such as coughing, acute rectal contraction, or assuming an upright position.

The puborectalis muscle originates from behind the pubic symphysis and extends posteriorly to loop around the rectum just proximal to the anal canal. The puborectalis tugs the rectum anteriorly and creates an angle between the rectum and the anal canal, the *anorectal angle*. This kink in the fecal pathway aids in continence (234,235). Conversely, failure of the puborectalis to relax appropriately, with persistence of an acute anorectal angle, has been associated with inability to defecate (236). The IAS, the EAS, and the puborectalis work together synergistically to maintain continence and are collectively named the *anal sphincter mechanism*.

The mucosa at the proximal end of the rectum and anal canal (anorectal junction) is rich in sensory receptors. This allows for socially critical judgments about the phases of the matter therein: liquid, solid, and gaseous material. The rectoanal inhibitory or sampling reflex allows a sample of the rectal contents to come into contact with this sensory zone. The *rectoanal inhibitory reflex* consists of a transient relaxation of the IAS stimulated by a rise in rectal pressure. A simultaneous increase in EAS tone, the *guarding reflex*, occurs to preserve continence while sensory receptors of the anorectal junction appraise the contents. The rectoanal inhibitory reflex occurs during sleep and throughout the day, usually at a subconscious level.

## Regulation of Gastrointestinal Function

Fortunately, many of the organs, tissues, and cells of the gastrointestinal system operate autonomously. Regulatory influences include the parasympathetic and sympathetic nervous systems, the enteric system within the gut, and endocrine, myogenic, and intraluminal cues. Preliminary knowledge is available but further investigation is required. Rudimentary explanations are offered so that the reader may exploit these systems therapeutically in neurogenic bowel management. The variety of these regulatory influences act in concert and interact in feedback loops. They can be explained from the gut lumen out.

## INTRALUMINAL CONTENT

The intraluminal contents can affect gastrointestinal function through alteration of the physical characteristics of stool, bacterial action, and the effects of various substances on mucosal receptors. The physical characteristics of the fecal mass have an important effect on colonic motility and defecation efficiency. The typical Western diet, deficient in fiber, results in small, hard, often scybalous stool that is difficult for the colon to propel and the rectum to evacuate. The effect of stool consistency on rectal evacuation has been well studied in able-bodied subjects (237,238). Dry, hard stool is not compressible; breaks apart; and contributes to high friction against the colonic wall. These stools produce difficulty with evacuation.

Addition of vegetable fiber to the diet increases stool volume and moisture content, which increases plasticity and decreases transit time (239). With increased dietary fiber, fecal microbial mass also increases (240). Bacterial fermentation of indigestible fiber within the colon generates short-chain fatty acids. These short-chain fatty acids are passively absorbed by colonic mucosa and may be oxidized as an important energy source (241). Bacteria also are important in the metabolism of bile salts. Bile salts stimulate colonic motility and may play a role in the hypermotility of patients with the irritable bowel syndrome (242).

Furthermore, the luminal content also can affect gastrointestinal function by the stimulation of specific mucosal receptors. Five types of gastrointestinal sensory receptors are known to exist. These respond to mechanical, chemical, osmotic, thermal, or painful stimuli.

## INTRINSIC OR ENTERIC NEURAL REGULATION

The enteric intrinsic nervous system is embedded in the wall of the gut and runs the length of the digestive tube, from the pharynx to the anus. Meissner's plexus is distributed throughout the submucosa and transmits local sensory and motor signals to Auerbach's plexus, autonomic ganglia, and the spinal cord. This intrinsic nervous system includes Auerbach's plexus (intramuscular myenteric) distributed between the longitudinal and circular muscle layers. The enteric nervous system is organized into three levels:

Afferent neurons, which gather sensory information and relay it to an array of interneurons

Interneurons, which process information locally, integrate the incoming sensory information, and coordinate local motor and secretory responses

Efferent neurons, which exert their influence on target cells, such as secretory, absorptive, or muscle cells

The enteric nervous system integrates sensory information from the contents and coordinates local and distant secretion and peristalsis. Ablation of all enteric nervous activity by the neurotoxin tetrodotoxin causes the colon to contract, the

rectum to undergo tonic and phasic contractions, and the IAS to contract tonically (243). Thus, it appears that the major effect of the enteric nervous system on the lower gastrointestinal tract is to provide an inhibitory influence.

## EXTRINSIC OR EXTRAINTESTINAL NEURAL REGULATION

Extrinsic neural influences provide overall coordination of intestinal reflexes as well as integration of the gastrointestinal tract with the whole organism. Sensory receptors in the gut may send afferents directly to the CNS, to prevertebral sympathetic ganglia, or to interneurons within the gut wall. The sensory information may be processed within the CNS, the prevertebral ganglia, or the enteric nervous system (Fig. 51-8). In fact, the enteric nervous system contains a greater number of neurons than the spinal cord (244). This is no surprise when the complexity and variety of gastrointestinal functions controlled by the enteric nervous system are considered. The important regulatory role of the enteric nervous system also is apparent in the organization of visceral efferents from the CNS. All efferents, except those to striated muscle in the

**FIGURE 51-8.** General organization of the enteric nervous system. Sensory fibers in the gut send afferents to the central nervous system (CNS) through the vagus nerve (cell bodies in nodose ganglia) or the sympathetic nerves (cell bodies in the dorsal root ganglia), prevertebral ganglia, and interneurons within the gut wall. Input may be processed and efferent fibers sent to effector cells at all three levels. The only efferent neurons that do not involve the enteric nervous system are the  $\alpha$ -motor neurons that innervate the striated muscle at both ends of the gut (i.e., cricopharyngeus and external anal sphincter).

pharynx or EAS (i.e.,  $\alpha$ -motor neurons), synapse with enteric interneurons before reaching an effector cell.

The gastrointestinal tract receives both parasympathetic and sympathetic nervous system innervation. The function of the parasympathetic efferents is complex. Separate groups of vagal preganglionic fibers may innervate inhibitory or excitatory neurons in the same organ. Therefore, whole-nerve stimulation may produce excitatory as well as inhibitory effects in the same organ. For example, transection of the vagus at the level of the lower esophagus (i.e., truncal vagotomy) has been used as treatment for peptic ulcer disease. Gastric acid secretion is diminished to a variable extent, and gastric motility is significantly impaired; however, small bowel and colonic motility are largely unaffected. Injury to the inferior splanchnic nerve (parasympathetic S2-4) results in impaired defecation and constipation (245). The function of the sympathetic nerves is generally to cause inhibition of motor and secretory activity and contraction of gastrointestinal sphincters. Sympathetic stimulation leads to adynamic ileus and decreased bowel activity. Although surgical sympathectomy has little clinical effect on bowel function in humans, diarrhea has been reported in animal models (246).

The striated muscle of the pharynx and the EAS is innervated by  $\alpha$ -motor neurons directly from the CNS. The cell bodies of the  $\alpha$ -motor neurons to the EAS are located in the anterior horn cells of spinal segments S2 through S4. Their axons are carried in the pudendal nerve. Injuries to the pudendal nerves or the sacral cord produce flaccid paralysis of the pelvic floor along with the external sphincter.

As can be inferred from the previous discussion, the regulatory mechanisms for gastrointestinal function are highly interdependent and frequently redundant. Loss of any individual component does not necessarily result in an identifiable syndrome. In fact, the inherent automaticity of the gut often allows it to function quite well in the absence of all extrinsic control. The effects of loss of extrinsic neural control (i.e., neurogenic bowel) are most apparent at the two ends of the gastrointestinal tract, where complex voluntary behaviors occur. The primary function lost with neurogenic bowel is voluntary control over defecation.

## GASTROINTESTINAL HORMONES

The gastrointestinal hormones influence activity in three systems throughout the alimentary canal. This influence is communicated by blood-borne chemical messengers (i.e., endocrine action) and secondarily transmitted by locally released messengers that traverse the interstitial space to reach a target cell (i.e., paracrine action). A third chemical messenger system, even more specific in its location of activity, is the neurocrine system. These neuropeptides are active only at the nerve terminals where they are released. The central role of neuropeptides in both neural and endocrine function illustrates the overlap and inseparability of these two systems.

Our understanding of the neuroendocrine potential of the colon has progressed much over the last decade (247).

The colon and rectum harbor peptides and amines that come from enterochromaffin cells in rectal crypts and enkephalinergic neurons in the myenteric plexus (247). The colon may be a source of enterogastrone, which is secreted in response to intracolonic nutrients and reduces gastric acid secretion from the stomach. Locally acting neuropeptides, including intestinal peptide, substance P, and GRP/bombesin, stimulate secretion of ions. Conversely, somatostatin, opioid peptide, and neuropeptide stimulate absorption.

## Transit and Motility

Studies of colonic transit time in people with SCI generally have shown a prolongation of total colonic transit time that is predominantly caused by slowing through the rectosigmoid segment (248,249). Interpretation of this finding is difficult because transit time studies cannot differentiate slow transit through the rectosigmoid because of altered colonic motility from slow transit because of infrequent or inefficient evacuation of the rectum. In our SCI population, bowel care was performed at a mean interval of approximately 2 days; the interval between bowel movements in a neurologically intact control group was 1 day. Because any movement in the rectosigmoid colon between bowel-care days would not be expected, the difference between SCI and controls may simply be related to the frequency of bowel care and bowel movements. Furthermore, Kellow et al. have demonstrated that distention of the rectum slows intestinal transit in both the fasting and fed states. Inhibition of contraction in one portion of the intestinal tract by distention of another (i.e., intestinointestinal, intestinocolic, and colocolic reflexes) was first reported 50 years ago (250). Interestingly, these reflexes are mediated in the prevertebral ganglia, not the spinal cord, so they likely would be unaffected by SCI (251).

Attempts to describe the effect of SCI on colonic motility by measurement of electrical or pressure events have yielded inconsistent results. Connell et al. (252), measuring intraluminal pressure waves, concluded that people with injury levels above T9 had decreased rectosigmoid motor activities, whereas those with lesions below T9 had increased motor activity. However, Aaronson et al. (253) found an increase in rectal myoelectric activity in a disparate group of six people with SCI when compared with neurologically intact controls. Glick et al. (254) found no change in myoelectric activity when nine people with SCI were compared with controls. Interpretation of these studies is plagued by many of the previously mentioned methodological problems. The study groups were small and uncontrolled for important variables such as time after injury, age, level and completeness of injury, and presence of gastrointestinal symptoms. Even if a consistent pattern of motility disorder could be found, it could as easily be caused by the inability to evacuate as by a primary motility problem.

## Fecal Continence

Fecal continence is achieved with a combination of structures that work together to prevent inadvertent passage of stool.

**FIGURE 51-9.** Balance of forces favoring continence or bowel evacuation. Physical character of stool is the pivotal variable that can shift the balance in either direction. Small, hard stool shifts the fulcrum to the left, and more force is required to evacuate. Soft, bulky stool causes the fulcrum to shift the opposite way.

These barriers are removable to allow bowel evacuation to occur. The current state, continence or evacuation, depends on the balance between those forces that favor expulsion of stool and those that resist it (Fig. 51-9). Expulsive forces include intra-abdominal pressure, colorectal contraction, elastic forces, and gravity. Resistive forces include the anorectal angle, anal canal tone contributed by the IAS and EAS, and friction. Stool consistency is a pivotal factor that can shift the balance in either direction. Small, hard stool is evacuated less completely and with more difficulty than soft, bulky stool (237,238), whereas even subjects with normal continence mechanisms may be incontinent when faced with large volumes of liquid stool as in during an acute diarrheal illness.

## CLINICAL EVALUATION

As with any patient, the evaluation begins with a complete history and physical examination. A request for symptoms guides the evaluation. Symptoms typically are vague; clues to their origin may be derived from a careful search for a relationship to exacerbating or remitting factors. The effect of body position, time of day, eating, bowel care, medications, and urinary function should be elicited (255). The presence of associated symptoms, such as autonomic dysreflexia, abdominal wall spasticity, fever, and weight change, should be noted. A gastrointestinal review of symptoms further clarifies function. A careful query of premorbid bowel function should be made, because neurologic lesions may alter the way that preexisting problems are manifested. Recognition of the impact of the symptom on the patient's ability to carry out important life activities is essential; neurogenic bowel dysfunction is notorious for detrimental impact on quality of life (256). Finally, the components of the bowel program should be systematically evaluated. A history of the type of diet—with special emphasis on fluid and fiber intake, use of laxatives, stool softeners, fiber supplements, and medications with anticholinergic properties—should be obtained. The frequency, duration, and technique of bowel care are elicited, as well as problems with stool consistency, lack of stool in the rectum at the time of stimulation, incontinence, and bleeding.

The physical examination is not only an assessment of the colon and pelvic floor but also includes a survey for associated

pathology, sensory/motor impairments, and activity limitations that could affect bowel care (220). Abdominal examination allows for motor assessment of the abdominal wall, percussion for tympany, palpation of the colon for impaction, and elicitation of symptoms (255). Pelvic floor innervation and function should be appraised with neurologic and rectal examination. The anocutaneous reflex is recognized with EAS contraction on anal skin contact. The bulbocavernosus reflex is elicited with penile head squeeze or clitoral pressure and the recognition of an increase in anal sphincter tone. Both these reflexes suggest an intact sensory (S3-4) to motor (S2) reflex arch (221). The rectal examination should assess for sensation, voluntary contraction, puborectalis tone, masses the rectal vault, and stool consistency. The examination is an opportunity for education and explanation of options for various techniques of bowel care. The Consortium for Spinal Cord Injury Medicine has published recommendations on “Neurogenic Bowel Management in Adults With SCI.” These give recommendations for assessment, management monitoring, and education concerning neurogenic bowel. A summary of these recommendations is provided in the appendix of this chapter. The full text can be downloaded at [PVA.org](http://PVA.org) or reviewed in *The Journal of Spinal Cord Medicine* (255).

## RECTODYNAMICS

To understand the effects of SCI on bowel evacuation, we designed a test to measure the opposing expulsive and resistive forces at work in the anorectum. We call the test *rectodynamics* because of its similarity to urodynamics, the study of bladder emptying (Fig. 51-10). Rectodynamics is performed by placing a triple-lumen catheter through the anus so that one pressure-measuring sideport is in the rectum and another is in the high-pressure zone of the anal canal. The third lumen is used to fill a balloon located in the rectum. A concentric EMG needle is placed in the EAS. Rectal and anal pressures, along with external sphincter EMG, are measured at rest and during stimulation of the anorectum by digital stimulation, the Valsalva maneuver, rapid rectal distention (i.e., air is rapidly injected and removed from rectal balloon to elicit the rectoanal inhibitory reflex), and slow, continuous filling of the rectal balloon with saline.

**FIGURE 51-10.** Rectodynamics setup. Expulsive forces (e.g., intra-abdominal pressure, colorectal contraction, rectal elasticity) are reflected by the pressure in the balloon in the rectum. Resistive forces are measured by the anal sphincter pressure. The contribution of the external sphincter is reflected by the EMG activity. Pressures are measured at rest and during stimulation by anal stretch (i.e., digital stimulation), rapid rectal stretch (i.e., rectoanal inhibitory reflex), and continuous infusion of saline into the rectal balloon.

The typical features of rectodynamic study of an asymptomatic person with upper motor neuron SCI are illustrated in Fig. 51-11A. During continuous filling of the rectal balloon, the intermittent rises in rectal pressure (i.e., rectal contractions) are invariably linked with decreases in anal canal pressure. When the rectal threshold pressure is reached (20 to 30 cm H<sub>2</sub>O), the external sphincter EMG becomes silent, and anal pressure decreases toward zero. The rectal pressure rises slowly until the rectal reservoir capacity is overcome (usually at 150 to 300 mL) and then rises rapidly until anal pressure is overcome and spontaneous evacuation of the balloon occurs.

## BOWEL EVACUATION MECHANICS

In neurologically intact people, the sequence of defecation begins with the perception of rectal fullness. This often occurs in response to a giant migratory contraction that pushes stool into the rectum. Rectal distention may be perceived at volumes as low as 10 mL by stretch receptors in the rectal wall, puborectalis muscle (257), and the pelvic floor. Continued rectal distention triggers rectal contraction and the rectoanal inhibitory reflex (258). Frenckner, while studying a small group of SCI patients, found that distention of the rectum with small volumes caused increased activity of the EAS (i.e., guarding reflex), whereas distention with large amounts caused the EAS to totally cease its electrical activity (232). This cessation of EAS activity rarely is seen in neurologically intact subjects. We have found that the volume at which the cessation of EAS activity

occurs is variable and probably related to rectal capacity but that the intrarectal pressure at which it occurs is quite constant (20 to 30 cm H<sub>2</sub>O; see Fig. 51-11A). There is a subgroup of patients with upper motor neuron lesions in whom EAS activity is aberrantly linked to rectal pressure (see Fig. 51-11B). In these patients, the spikes in rectal pressure that occur during dynamic rectal filling are met by increases in anal pressure. There is a failure to “turn off” EAS sphincter activity despite the presence of rectal pressures greater than 100 cm H<sub>2</sub>O. We call this pattern *anorectal dyssynergia* by analogy with detrusor-sphincter dyssynergia of the bladder. These SCI patients usually have significant difficulty with bowel evacuation.

If the choice is made to defecate, the sitting position is assumed. Sitting makes the angle between the rectum and anal canal less acute (259). In the able bodied, a rise in intra-abdominal and perhaps intrarectal pressure is generated by closing the glottis to retain a full breath in the chest. The abdominal muscles are contracted and the diaphragm is pulled down. Neurologically intact people often are able to increase intrarectal pressure by 100 cm H<sub>2</sub>O or more with a Valsalva maneuver. Persons with upper motor neuron SCI often initiate bowel evacuation with digital stimulation. Digital rectal stimulation is done by introducing the entire length of the gloved and lubricated finger into the rectum and dilating the distal rectum by moving in a circular funnel pattern. This key unlocks the sphincter mechanism, stretches the puborectalis, and provides a stimulus for peristalsis (220,255,260). Digital rectal stimulation results in the transient loss of approximately 75% of resting anal tone and presumably further straightens the anorectal angle. Expulsive force is added by performance of a Valsalva maneuver as well as the addition of external abdominal compression. The ability to elevate intra-abdominal pressure with the use of these techniques is closely related to the level and completeness of SCI. Patients with C5 to C6 level injuries rarely can generate intra-abdominal pressures greater than 10 cm H<sub>2</sub>O.

The most common rectodynamic finding in patients with symptomatic difficulty with bowel evacuation is a failure to generate expulsive forces that are sufficient to overcome the residual tone of the normal, fully relaxed sphincter mechanism. These patients typically have long-standing cervical cord injuries, often with associated megacolon and megarectum. In these patients, the relationship between rectal pressure and anal relaxation remains intact, although it can take rectal volumes greater than 500 mL to generate enough rectal stretch to trigger anal relaxation. Rectal volumes of 100 to 150 mL usually are sufficient to turn off the anal sphincter mechanism.

Once evacuation is initiated, the entire left colon may empty by mass peristaltic action, or the fecal bolus may be passed bit by bit. The presence of an anocolic reflex (i.e., stool passing through the anus causes colonic contraction) has been postulated but not proven. Stool consistency is probably the major determinant of the pattern of defecation. Stool consistency is of even greater importance in SCI patients, in whom the balance between expulsive and resistive forces is so tenuous.

**FIGURE 51-11.** Rectodiagnostics study. During the tracing, the balloon in the rectum is being filled with saline at a constant rate (20 mL/min). **A:** Normal evacuation pattern after spinal cord injury. (1) Small rises in rectal pressure (i.e., rectal contractions) are invariably linked to anal pressure relaxation. Later contraction does not show linked relaxation because anal pressure cannot go below zero. (2) Gradual rise in rectal pressure becomes rapid when rectal reservoir capacity is overcome (usually 150 to 300 mL). (3) When rectal threshold pressure (20 to 30 cm H<sub>2</sub>O) is reached, anal pressure goes to zero. (4) Spontaneous evacuation of the balloon occurs when expulsive forces exceed resistive forces. **B:** Dyssynergia. (1) Loss of normal anal relaxation with rectal contraction. In this patient, there is total loss of coordination between the rectum and the anus. (2) Anal pressure fails to go to zero when the normal threshold (20 to 30 cm H<sub>2</sub>O) of rectal pressure is reached. (3) No spontaneous evacuation of the rectal balloon occurs despite rectal pressures of 100 cm H<sub>2</sub>O. Anal pressures increase concomitantly. (4) Spikes of EMG activity reflect contractions of the striated external anal sphincter. These contractions occur inappropriately and cause an elevation in anal pressure.

### Neurogenic Bowel Function

Supraspinal bowel dysfunction occurs with lesions rostral to the pons. Voluntary defecation depends on an accurate perception of the need to defecate as well as the necessary motor function to position over a toilet and to initiate the complex motor activity of bowel evacuation. A failure to perceive rectal fullness is common in the elderly and may manifest as overflow incontinence around a fecal impaction (261). Although disorders of continence and bowel evacuation are not uncommon after stroke, few distinct syndromes have been described. One syndrome, frontal lobe incontinence, is caused by lesions involving the anterior cingulate gyri (262). Patients with frontal lobe

incontinence are said to have no awareness of bladder or rectal fullness. A pontine defecation center, analogous to the pontine micturition center, has been postulated but not proven (263). Patients with Parkinson's disease and multiple sclerosis often have disordered bowel evacuation; however, it may be difficult to factor out the effects of immobility, diet, and medications in these cases.

Upper motor neuron bowel dysfunction occurs with lesions between the pons and the sacral spinal cord. This is the type of dysfunction most common in patients with C1 through T10 SCI. Associated deficits in function include sensory deficit for perception of fullness, a spastic pelvic floor that retains stool,

and less effective peristaltic patterns (221). The gastrocolonic response is preserved after SCI. This is the increase in peristalsis in the large and small intestine in response to a meal. The gastrocolonic response has been demonstrated to be preserved after complete SCI, although it may be somewhat less robust as compared with able-bodied controls (264). A bowel program is a unique plan designed to effectively eliminate stool and prevent incontinence. The components are fluid intake, diet, exercise, medications, and scheduled bowel care (255). Bowel care is the procedure for assisted defecation. Through empirical manipulation of diet, hydration, medications, and stimulation techniques, a balance is maintained between continence and evacuation.

Using the rectodynamics technique, we have identified two patterns of bowel evacuation mechanics that are associated with an inability to undergo satisfactory reflex evacuation: anorectal dyssynergia and insufficient expulsive forces. In both situations, spontaneous evacuation of the saline-filled balloon rarely occurs. In asymptomatic patients, spontaneous evacuation at volumes of 150 to 300 mL is the rule. Patients with insufficient expulsive forces tend to be older and to have had their SCI longer than patients with anorectal dyssynergia. It is attractive to postulate that both patterns are different stages of the same process. Chronically obstructed evacuation from dyssynergia may result in an end-stage dilated and decompensated rectum that is unable to generate a sufficient expulsive force. Against this theory is the finding that many patients with the insufficient expulsive force pattern retain a normal linkage between rectal and anal pressures, albeit at much higher volumes. Because all patients with insufficient expulsive force have cervical injuries, it is tempting to implicate a specific neurophysiologic cause, such as an overabundance of sympathetic input, although it is difficult to explain why the majority of patients with complete cervical injuries do not manifest this pattern. A more likely association with cervical injuries is that with denervation of the abdominal wall, only minimal increases in intra-abdominal pressure can be generated. Although these studies do not reveal the underlying pathophysiological process of neurogenic bowel, they do provide a practical basis for thinking about the management of patients with neurogenic bowel.

### Gastrointestinal Problems After Spinal Cord Injury

It has long been clear to clinicians that gastrointestinal symptoms are very common in the chronic phase after SCI. Colonic and pelvic floor function are entwined in etiquette and governed by social norms. The need for scheduled bowel care and fears of unanticipated evacuation are life limiting (256). Glickman and Kamm evaluated 115 consecutive outpatients with chronic SCI. Eighty-nine were male, the mean duration of injury was 62 months, and the level of injury was categorized as 48% cervical, 47% thoracic, and 5% lumbar. In this group, 95% required at least one therapeutic method to initiate defecation, half were dependent on others for toileting, and 49% took more than 30 minutes to complete bowel

care (265). In a prospective study carried out by the Palo Alto Veterans Affairs Medical Center Spinal Cord Injury Service, chronic gastrointestinal problems that were severe enough to alter lifestyle or require chronic treatment occurred in 27% of subjects. The limited way in which people with SCI can manifest symptoms resulted in symptoms that were characteristically nonspecific. The most common problems were difficult bowel evacuation (20%) and poorly localized abdominal pain (14%). The term *pain* was used in its most general sense and was defined as a distressing sensation in a particular part of the body. Presumably, the pain sensation was carried to the brain by means of autonomic afferents (266).

Difficult bowel evacuation was said to be present in patients who required more than 60 min/d for their bowel care or needed manual disimpaction more than once a week. When managing persons with SCI, the term *constipation* is avoided because it is and has varied implied meanings. Specific descriptions are preferred, such as prolonged defecation, insufficient results, or abdominal fullness (256). The impact of problems with bowel evacuation on quality of life is formidable. In patients with difficult bowel evacuation, bowel care routinely occupies a significant part of the day, greatly restricted diets are adopted to minimize symptoms, and emergency trips to a physician for disimpaction are common. Episodes of dysreflexia, rectal bleeding, and incontinence from overtreatment with laxatives also occur frequently.

There are a few surgical options to improve success in neurogenic bowel management should conventional bowel care be ineffective (267). The appendicocostomy stoma is constructed by bringing the appendix through the abdominal wall. This stoma is irrigated with a 100 to 500 mL of saline to trigger defecation. This procedure has been used most successfully in patient populations with spina bifida (268). A few carefully selected patients with SCI who have benefited from the catheterizable stoma have been reported (269). Colostomy is an elective procedure that can improve independence in bowel care and enhance quality of life (270–272). The decision for surgical adaptation requires interdisciplinary evaluation (255) to explore implications of surgical risk (270), body image, and functional outcome. Interdisciplinary trials of various appliances and methods for self-management can lead to optimization of stoma location and choice of equipment. Colostomy has been performed with good success in the subgroup of these patients with the most severe disability (270). In patients with severe difficulty with evacuation, unresponsive to alterations in the bowel program, colostomy can shorten the time needed for bowel care and enhance self-efficacy and quality of life (271,273).

Stone and collaborators prospectively reviewed gastrointestinal complications in a cohort of patients with acute and chronic SCI (270). Incontinence is more common in patients with lower motor neuron than upper motor neuron bowel except during diarrheal illness or as a result of overtreatment for difficult bowel evacuation. Autonomic dysreflexia arising from the gastrointestinal tract occurred in almost one half of the subjects with lesions above T6 at some time but was

rarely a significant problem by itself. Fecal impaction was the most common precipitating cause of autonomic dysreflexia. Other less common causes were massive abdominal distention and routine digital rectal stimulation. Rectal bleeding during bowel care occurred in 74% of subjects. The majority of these patients were treated with hemorrhoidal bands or expectant management. Twelve percent eventually required operative hemorrhoidectomy. Esophageal reflux symptoms were present in 24% of subjects, and 10% of patients had a proven peptic ulcer. These rates are similar to those seen in the nondisabled population (270).

Gastrointestinal problems have special significance for people with SCI. Some problems, such as autonomic dysreflexia and ventilatory insufficiency caused by massive abdominal distention, are life-threatening problems that are unique to SCI patients. Other problems are shared with the nondisabled population but are associated with disproportionate morbidity when they occur in people with SCI. Twenty-three percent of SCI patients required an admission to the hospital for evaluation or treatment of a chronic gastrointestinal problem. Absence of specific symptoms made emergency operations the rule rather than the exception for problems such as peptic ulcers and gallstones.

Stone et al. (270) further noted that chronic gastrointestinal problems usually do not develop for several years after injury. This finding is particularly significant because it suggests that these problems potentially are preventable. The situation may be analogous to that of the urinary tract in years past, when improvement in chronic care protocols has greatly reduced morbidity. For example, if chronic rectal overdistention eventually impairs the ability to evacuate, techniques to reduce rectal distention, such as more frequent bowel care, may be of benefit. In this way, decompensation of the rectum may be analogous to detrusor decompensation from chronic bladder overdistention.

### Medical and Rehabilitation Management

The approach of evaluation and intervention to improve gastrointestinal function after SCI should be interdisciplinary and address all domains of disablement (221). The World Health Organization has recently redefined disablement domains that address the organ (impairment), person (activity limitation), and the person as related to the environment (barriers to participation). A spectrum of inquiry that spans organ function and task capabilities of the person and needs for full community integration will lead to the most effective treatment (221).

Utilization of the entire interdisciplinary team for assessment and goal setting integrates bowel management into the comprehensive rehabilitation plan. Overall bowel management is outlined in the bowel program, which includes the following components: diet, fluid intake, medications, physical activity, and a schedule for bowel care. Bowel care is the procedure for assisted defecation with one or more of the following components: positioning, assistive devices, rectal stimulation or trigger for defecation, and assistive maneuvers (abdominal massage) (221,255).

All components of the bowel program should be designed for maximal performance. People with SCI, particularly those with tetraplegia, have very little capability to overcome resistive forces and expel stool with bowel care. Stool consistence should be titrated with diet and medications (see Fig. 51-9). Adjustments in the bowel program that may be trivial in the nondisabled population can shift the balance significantly. Stool consistency is a pivotal variable. A diet containing 15 to 30 g of dietary fiber per day should be encouraged (221,255,271). Wheat bran and psyllium make the stool more pliable by increasing the fecal water content (274). Other helpful interventions include upright bowel care to utilize gravity, abdominal binders, daily osmotic laxatives, increased frequency of bowel care, more frequent digital stimulation, and stronger triggering medications.

Avoidance of colorectal overdistention is desirable because rectal distention is known to decrease intestinal transit by the colocolic reflex. Frequent bowel care (i.e., every 1 to 2 days) will avoid colonic distention with stool and may also enhance colonic transit by the hypothetical anocolic reflex. A preliminary intervention to promote bowel evacuation is movement of the sigmoid contents into the rectum. This may be accomplished by timing bowel care after a large meal to take advantage of the gastrocolonic response or by giving an oral laxative the day before. SCI persons with upper motor neuron bowel have SCI lesions above the conus and retain bulbocavernosus and anocutaneous reflexes.

The basic bowel care procedure for upper motor neuron neurogenic bowel has been broken down into steps (Table 51-4) and presented in patient education booklets (255) and a film, *Accidents Stink!: Bowel Care 202* (275). Rectal minienemas or suppositories and digital stimulation trigger and facilitate efficient bowel evacuation. A suppository or the contents of a minienema are first inserted as high as possible into the rectal

**TABLE 51.4 Steps of Bowel Care: Reflexic Neurogenic Bowel**

1. Getting ready and washing hands: Empty bladder.
2. Setting up and positioning: Transfer to a toilet or commode. If you don't sit up, lie on your left side.
3. Checking for stool: Remove any stool that would interfere with inserting a suppository or minienema.
4. Inserting stimulant medication: Using a gloved and lubricated finger or assistive device, place the medication right next to the rectal wall.
5. Waiting: Wait about 5–15 min for the stimulant to work.
6. Starting and repeating digital rectal stimulation: To keep stool coming, repeat digital rectal stimulation every 5–10 min as needed, until all stool has passed.
7. Recognizing when bowel care is completed: You'll know that stool flow has stopped if (a) no stool has come out after two digital stimulations at least 10 minutes apart, (b) mucus is coming out without stool, or (c) the rectum is completely closed around the stimulating finger.
8. Cleaning up—Wash and dry the perianal area.

vault and positioned against the mucosal lining. Suppositories containing bisacodyl are frequently used (276,277). They stimulate the sensory nerve endings, resulting in local and conal mediated reflex increases in peristalsis, frequently signaled by flatus. It generally takes 15 to 60 minutes for passage of the first flatus, which is followed shortly thereafter by stool flow (221). A significant reduction in the duration of bowel care can be achieved by using polyethylene glycol-based (PGB) bisacodyl suppositories rather than hydrogenated vegetable oil-based (HVB) bisacodyl (276,277). The average time to first flatus was 10 minutes with the PGB suppository compared with 37 minutes with the HVB suppository. The average total bowel-care time was 46 minutes with the PGB suppository compared with 85 minutes with the HVB suppository (278). Suppositories containing sodium bicarbonate and potassium bitartrate are sometimes used. With this suppository, there is a chemical reaction that releases carbon dioxide. The colonic expansion from this reaction often initiates a rectal-anal reflex. However, use of this type of suppository usually requires significant anal sphincter tone to prevent the carbon dioxide from being expelled before causing expansion within the rectal vault. Glycerine suppositories are often used as a transition from bisacodyl suppositories to no suppositories and digital stimulation. Glycerine draws water into the stool to soften it, provides a mild irritant stimulus to trigger defecation, and lubricates the rectum to reduce resistance for expulsion.

Following an adequate time for the suppository to take effect, digital stimulation is initiated. If a person is having difficulty with autonomic dysreflexia during digital stimulation, pretreatment with topical application of viscous 2% lidocaine may be beneficial. If no stool is present in the rectal vault, stimulation may be repeated a few minutes later. If stool still is not present in the rectal vault, a small-volume saline enema may be given to lubricate the rectum and create acute rectal distention. If this is still unsuccessful, a small-volume bisacodyl enema may be helpful to stimulate colorectal peristalsis.

Patients with lower motor neuron bowel typically have SCI lesions affecting the conus or cauda equina. Anal canal tone is reduced, anocutaneous bulbocavernosus reflexes are absent, and the pelvic floor may passively descend. Bowel care for lower motor neuron SCI typically consists of digital rectal stimulation and manual evacuation after the morning and evening meals. A study of bowel-care patterns of persons with SCI revealed that the average frequency of bowel care in persons with lower motor neuron bowel was twice per day, and the frequency of those with upper motor neuron bowels averaged three times per week (278).

Oral medications may also be used to potentiate the success of bowel care. Oral dioctyl sodium sulfosuccinate functions as a stool softener by having a detergent effect and increasing fluid accumulation in the stool. Oral senna or bisacodyl preparations are sometimes helpful 6 to 12 hours before bowel care. Their action is limited to the colon and felt to stimulate Auerbach's plexus (221,271).

In patients with difficult bowel evacuation, the first step is optimization of stool consistency with fluids, fiber, oral osmotic agents, or glycerin suppositories. If possible, anticholinergic

agents such as oxybutynin are discontinued. If rectodynamic studies show anorectal dyssynergia, applying viscous 2% lidocaine topically and providing a prolonged anal stretch occasionally are of benefit. If the rectodynamic study shows that a megarectum already exists, large-volume enemas (300 to 500 mL) may be necessary to provide the necessary rectal distention to raise rectal pressures and shut down anal sphincter activity. In those prone to autonomic dysreflexia, careful monitoring of blood pressure is necessary.

In patients who have failed all attempts to modify their bowel program, colostomy may provide remarkable relief (221,255,266,275). We currently reserve colostomy for patients with severe long-term disability, excessively long bowel care with poor results, and exhaustion of all nonsurgical options. Transit time studies are performed before colostomy. If markers accumulate in the rectosigmoid, a sigmoid colostomy is performed. If the entire colon is atonic, an ileostomy is performed.

Traumatic superficial mucosal erosion is by far the most common cause of bright red rectal bleeding after SCI. It usually is manifest as streaks of blood on the glove or stool. This should be distinguished from hemorrhoidal bleeding (i.e., bleeding from high-pressure vessels within hemorrhoids), which usually manifests as blood dripping into the commode or passage of clots. Traumatic erosion usually is treated conservatively. Hemorrhoids need only be treated when they cause a symptom such as bleeding, mucous soilage, or difficulty with anal hygiene. They should be kept clean, wiped with a solution or witch hazel, and supported on an air-filled cushion. A minimal evaluation for bright red rectal bleeding includes digital examination, anoscopy, and proctoscopy or flexible sigmoidoscopy.

Bright red rectal bleeding, when it occurs after SCI, tends to arise from circumferential mucosal excoriation rather than from a discrete site on a hemorrhoid. Therefore, treatment of the entire circumference of the anal canal may be necessary to eliminate bleeding. The traditional treatment has been rubber-band ligation of bleeding hemorrhoids. Patients must be aware that the likelihood of recurrent bleeding is high, that multiple applications may be necessary, and that complications, although rare, do occur. Transient episodes of autonomic dysreflexia have occurred at the time of banding, although all have been brief and self-limited (266).

Traditionally, in patients with irreducible hemorrhoidal prolapse (Grade 4), blood loss sufficient to cause anemia, or failure of rubber-band ligation, operative excisional hemorrhoidectomy is performed (279,280). A conventional surgical technique is used. To avoid manipulation of the fresh suture lines, however, we perform a full mechanical bowel preparation before surgery. No bowel care is performed for 4 days after operative hemorrhoidectomy.

A newer technique called Procedure for Prolapse and Hemorrhoids (PPH) may be an effective alternative. It involves using a surgical stapler to remove a circumferential ring of prolapsing mucosa just above the anorectal junction. In able-bodied individuals, it has been found to be faster and a much easier way to remove bleeding tissue and is associated with substantially less pain, shorter hospital stay, quicker return to normal

activities, and voiding difficulties than a conventional excisional hemorrhoidectomy. This technique may be especially useful for those with Grade 3 (rectal prolapse is manually reducible) or Grade 4 (rectal prolapse irreducible) hemorrhoids (281).

The frequency with which rectal bleeding occurs makes screening for colorectal cancer by testing for occult blood of little value. We screen patients older than 45 years with flexible sigmoidoscopy. If polyps or tumors are seen, a full colonoscopy is performed (266).

## APPENDIX: SUMMARY OF NEUROGENIC BOWEL MANAGEMENT RECOMMENDATIONS

From The Consortium for Spinal Cord Injury Medicine recommendations “Neurogenic Bowel Management in Adults With SCI” Reproduced with Permission from The Paralyzed Veterans of America. (255) (Please use the wording requested from PVA.)

The recommendations for assessment, management monitoring, and education concerning the neurogenic bowel are summarized below. The subsequent text contains the scientific evidence and supporting rationale for each recommendation.

### ASSESSMENT OF THE NEUROGENIC BOWEL

#### Assessment of Impairment and Disability

1. A systematic, comprehensive evaluation of bowel function, impairment, and possible problems should be completed at the onset of SCI and at least annually throughout the continuum of care.
2. The patient history should include the following elements:
  - Premorbid gastrointestinal function and medical conditions
  - Current bowel program, including patient satisfaction
  - Current symptoms, including abdominal distention, respiratory compromise, early satiety, nausea, evacuation difficulty, unplanned evacuations, rectal bleeding, diarrhea, constipation, and pain
  - Defecation or bowel care (assisted defecation procedure) frequency, and duration and characteristics of stool
  - Medication use and potential effect on bowel program
3. A physical examination should be done at the onset of SCI and annually thereafter. The examination should include
  - Complete abdominal assessment including palpation along the course of the colon
  - Rectal examination
  - Assessment of anal sphincter tone
  - Elicitation of anocutaneous and bulbocavernosus reflexes to determine if the patient has upper motor neuron (UMN) or lower motor neuron (LMN) bowel
  - Stool testing for occult blood beginning at age 50

#### Assessment of Function (Disability)

4. An assessment of knowledge, cognition, function, and performance should be conducted to determine the ability of the individual to complete bowel care or to direct a caregiver to complete the procedure safely and effectively. The assessment should include the following elements:
  - Ability to learn
  - Ability to direct others
  - Sitting tolerance and angle
  - Sitting balance
  - Upper-extremity strength and proprioception
  - Hand and arm function
  - Spasticity
  - Transfer skills
  - Actual and potential risks to skin
  - Anthropometric characteristics
  - Home accessibility and equipment needs

### MANAGEMENT OF THE NEUROGENIC BOWEL

#### Designing A Bowel Program

5. The bowel program should provide predictable and effective elimination and reduce evacuation problems and gastrointestinal complaints. Bowel programs should be revised as needed throughout the continuum of care.
6. Within established parameters of safety and effectiveness, the design of the bowel program should take into account attendant care, personal goals, life schedules, role obligations of the individual, and self-rated quality of life.
7. Bowel programs should be initiated during acute care and continued throughout life, unless full recovery of bowel function returns. Differences in bowel programs for reflexic and areflexic bowels include type of rectal stimulant, consistency of stool, and frequency of bowel care. To establish a bowel program:
  - Encourage appropriate fluids, diet, and activity
  - Choose an appropriate rectal stimulant
  - Provide rectal stimulation initially to trigger defecation daily
  - Select optimal scheduling and positioning
  - Select appropriate assistive techniques
  - Evaluate medications that promote or inhibit bowel function
8. A consistent schedule for defecation should be established based on factors that influence elimination, preinjury patterns of elimination, and anticipated life demands.
9. Prescribe mechanical and/or chemical rectal stimulation to predictably and effectively evacuate stool.
10. The use of assistive techniques should be individualized and their effectiveness in aiding evacuation should be evaluated. Push-ups, abdominal massage, Valsalva maneuver,

deep breathing, ingestion of warm fluids, and a seated or forward-leaning position are some of the techniques used to aid in bowel emptying.

## Nutrition

11. Individuals with SCI should not be placed uniformly on high-fiber diets. A diet history should be taken to determine the individual's usual fiber intake. The effects of current fiber intake on consistency of stool and frequency of evacuation should be evaluated. A diet containing no less than 15 g of fiber daily is needed initially. Increases in fiber intake should be done gradually, from a wide variety of sources. Symptoms of intolerance should be monitored, and reductions in fiber are recommended, if they occur.
12. The amount of fluid needed to promote optimal stool consistency must be balanced with the amount needed for bladder management. In general, fluid intake should be approximately 500 mL/d greater than the standard guidelines used to estimate the needs of the general public (National Research Council, 1989). Standard guidelines indicate that adult fluid needs can be estimated by either of the following formulas:

1 mL fluid/Kcal of energy needs + 500 mL/d  
or  
40 mL/kg body weight + 500 mL/d

## Managing The Neurogenic Bowel at Home or in the Community

13. Appropriate adaptive equipment for bowel care should be prescribed based on the individual's functional status and discharge environment.
14. Careful measures should be taken to avoid pressure ulcers and falls related to the use of bowel care equipment.
15. Adequate social and emotional support should be available to help individuals manage actual or potential disabilities and handicaps associated with neurogenic bowel.
16. All aspects of the bowel management program should be designed to be easily replicated in the individual's home and community setting.

## Monitoring Program Effectiveness

17. The following variables should be monitored during and documented after every bowel care procedure during hospitalization or when developing or revising a bowel program in any community setting:
  - Date and time of day
  - Time from rectal stimulation until defecation is completed
  - Total time for completion of bowel care
  - Mechanical stimulation techniques
  - Pharmacological stimulation
  - Position/assistive techniques

- Color, consistency, and amount of stool
- Adverse reactions
- Unplanned evacuations

18. When a bowel program is not effective (i.e., if constipation, GI symptoms or complications, or unplanned or delayed evacuations occur) and a consistent schedule has been adhered to, changes in the following components should be considered:
  - Diet
  - Fluid intake
  - Level of activity
  - Frequency of bowel care
  - Position/assistive techniques
  - Type of rectal stimulant
  - Oral medications
19. In the absence of adverse reactions and indicators for potential medical complications, the bowel care regimen should be maintained for three to five bowel care cycles prior to considering possible modifications. Only one element should be changed at a time.
20. When evaluating individuals complaining of bowel management difficulties, adherence to treatment recommendations should be assessed.
21. Colorectal cancer must be ruled out in individuals with SCI over the age of 50 years with a positive fecal occult blood test or with a change in bowel function that does not respond to corrective interventions.

# Pressure Ulcers

## SCOPE OF THE PROBLEM

### Definition

Tissue necrosis and breakdown is referred to by many terms including decubitus ulcers, bedsores, ischemic sores, and pressure sores. The term “pressure ulcer” is the most accurate nomenclature to describe both the cause and nature of soft tissue wounds, caused primarily by excessive applied pressure. This term will be used throughout this chapter. A critically important precursor to appropriate care is an accurate identification and classification of a soft tissue wound as a pressure ulcer. This definition has recently been updated by the National Pressure Ulcer Advisory Panel (NPUAP) to be a localized injury to the skin and/or underlying tissue usually over a bony prominence, as a result of pressure, or pressure in combination with shear and/or friction (1). This change takes into account an increasing body of evidence that pressure ulcers are generally multifactorial in origin. Furthermore, pressure ulcers are frequently associated with deep tissue injury that can be difficult to detect on initial examination, particularly in individuals with darker skin tones. The NPUAP has, therefore, also updated the guidelines for staging in order to provide clinicians with a standardized and reliable framework for classification (see “Assessment” below). Appropriate and effective care of pressure ulcers is essential in order to minimize further medical complications that can include amyloidosis, osteomyelitis, septicemia, and even death.

### Economic Implications

The presence of one or more chronic pressure ulcer has a significant negative impact, both on the individual’s health status and on the overall health care system. The total economic impact is hard to quantify. The most recent figures in the United States date from 1999 when the treatment costs were estimated to be in excess of \$1.3 billion annually (2). More recently, in 2004, Bennett et al. (3) found that the annual cost of treating pressure ulcers in the United Kingdom was approximately 4% of the total health care expenditure (1.4 to 2.1 billion GBP), equivalent to around \$4 trillion per annum in February 2008. This major trend for increasing costs may continue as the overall population at risk for chronic wounds increases with changing demographics, in particular an increasing aged population with reduced mobility. Cost containment will require continuous improvements in clinical care for early identification, prevention, and treatment of pressure ulcers. Lyder et al.

(4) found that implementing comprehensive prevention programs can significantly reduce the incidence but that costs are not significantly reduced. Prevention intervention strategies should, therefore, be based on risk stratification.

### Incidence and Prevalence

Pressure ulcers are a very common cause of morbidity and even mortality. No central registry exists and many pressure ulcers may go unreported, leading to higher rates of both morbidity and mortality (5). Incidence and prevalence vary widely, both between studies and across different health care settings. For example, in the United States the prevalence of pressure ulcers in acute care hospitals has been reported to be between 3% and 69%, with annual incidence rates of 1% to 29% (6–11). More recent studies in Swedish and Canadian acute health care settings have found the overall prevalence rates of 29% to 33% (12,13).

In the U.S. long-term care facilities and nursing homes, prevalence rates from 1% to 35% have historically been noted, with annual incidence rates of 10% to 38% (14–16). Brandeis et al. reported that pressure ulcer development was associated with a 4.5 times greater risk of death for elderly nursing home residents than for those who did not have pressure ulcers but had the same risk factors (17). The prevalence of pressure ulcers among the outpatient population has not been well-defined, although studies have reported similarly varying rates (18).

These figures should be viewed cautiously; some variations, particularly in smaller studies with lower reported incidence rates, may be due to factors such as pressure ulcer definition, study population characteristics, and data source, for example, retrospective chart review or self-report (19). For example, in some studies over 45% of reported pressure ulcers were classified as Stage 1, whereas in others Stage I pressure ulcers were not included. Although Stage I pressure ulcers may not appear clinically severe, and are generally readily treatable, it has been found that these ulcers are an important warning of potential future deterioration (20), and they should therefore always be taken seriously.

Although there is paucity of recent, reliable, and widely available data for U.S. health care facilities, there is a growing assumption, particularly reflected in regulatory and quality management guidelines, that the development of *any* pressure ulcer is evidence of negligent care by a health care provider or health care system (21). Increasing public awareness has provided the perception that pressure ulcers are preventable

and readily treatable. The Centers for Medicare & Medicaid Services (CMS) guidelines mandate that any resident who enters a nursing home without a pressure ulcer must not develop pressure ulcers unless the individual's clinical condition is such that they were "demonstrably unavoidable" (22). Any resident who has a pressure ulcer must receive necessary treatment to promote healing, prevent infection, and prevent new ulcers from developing. Both federal and state surveyors ensure compliance with all aspects of the mandate. Penalties for noncompliance and/or violations can be severe, including fines, loss of financial support, and even immediate closure of the facility. This environment dictates that all clinical practitioners be highly educated in all aspects of pressure ulcer care for their patients.

## ANATOMY AND PATHOPHYSIOLOGY: NORMAL SKIN

The skin is the largest organ in the integumentary system, the external covering of the body. It has multiple functions, including protection of the body from trauma, dehydration, and microorganisms; thermoregulation, excretion of waste products through perspiration, and sensory perception. The skin also produces vitamin D through exposure to ultraviolet light. Therefore, it is vital to our health and damage to the skin may have potentially serious consequences.

There are two main layers to the skin: the epidermis and the dermis. There are subcutaneous tissues underlying the dermal layer. The dermis is about four times the thickness of the epidermis and consists of collagen fibers, blood vessels, lymphatic vessels, sweat glands, hair roots, and sensory nerves. Embryologically, this layer is derived from the mesoderm. The main function of the dermis is to support the epidermis, and provide strength and elasticity to the skin. There are two main layers in the dermis, the superficial papillary dermis and the deeper reticular dermis. The papillary dermis consists of loose connective tissues, capillaries, and elastic fibers, while the reticular dermis consists of dense connective tissues, elastic fibers, larger blood vessels, fibroblasts, mast cells, sensory nerves, and lymphatic vessels. This layer is essential for blood supply and sensory perception. The subcutaneous tissues lie between the dermis and the underlying muscle and bone. They consist of adipose tissues and their main function is to provide insulation and storage of nutrients.

The blood supply of the skin comes from the underlying structures, supplying the various structures in the skin along the way, and is crucial for thermoregulation. The blood supply from the bone travels into the skin, supplying the muscles, fascia, nerve, and connective tissues. The blood vessels in the skin anastomose and form a horizontal network of blood vessels in the dermis. Blood flow to the skin is very high and allows effective heat dissipation from the skin through vasodilation of the blood vessels. Conversely, vasoconstriction in the skin will lead to diminished blood flow and thus reduced heat loss and a cool skin surface.

## WOUND HEALING

Normal physiological wound healing is a complex, dynamic process that can be defined as comprising four main phases: hemostasis, inflammation, proliferation, and tissue remodeling (23,24) (Fig. 52-1). Inflammation can be further divided into early and late inflammation. Similarly, proliferation consists of both granulation tissue and extracellular matrix (ECM) formation. The entire sequence of events exhibits substantial overlap of the various phases, with each phase characterized by different predominant cell types.

Immediately following injury, the healing response begins with the activation of the coagulation cascade and the creation of a blood clot (25), producing hemostasis and preventing further blood loss (26). Various chemotactic factors, including platelet-derived growth factor (PDGF), stimulate the migration of blood neutrophils and monocytes, helping to initiate the second phase of healing, the inflammatory response (27).

Inflammation is responsible for containing, neutralizing, diluting, or walling off the injurious agent or process (28). Acute inflammation lasts only minutes to days depending on the extent of injury as leukocytes, predominately neutrophils (28), invade the wound and clear it of debris (25,27). As the neutrophils diminish, the wound moves to the chronic inflammation phase with increased activity of macrophages and lymphocytes. Macrophages produce several biologically active enzymes and cytokines, including collagenases that phagocytose cell debris, senescent neutrophils, and devitalized tissue in the wound region. This debrides the wound and promotes wound healing. Interleukins and tumor necrosis factor (TNF) concurrently promote angiogenesis and stimulate fibroblasts activity (28), leading to the wound transitioning to the proliferative phase.

Granulation tissue formed during the proliferative phase of healing provides a temporary weak tissue layer in the wound. Granulation tissue is so called because of the pink, soft granular surface appearance (27–29). New blood vessels are produced by budding or sprouting from pre-existing vessels in a process known as neovascularization or angiogenesis (28).

**FIGURE 52-1.** Phases of normal wound healing.

**FIGURE 52-2.** Primary locations for pressure ulcers.

Angiogenesis is essential for granulation tissue formation and improves the overall tissue perfusion (30). Another key aspect of the proliferation phase is reepithelialization: Migration and proliferation of keratinocytes from the wound edges leads to the formation of a thin epithelial layer over the developing granulation tissue (27). In a full thickness, nonsutured wound the rate of reepithelialization is thus inversely related to the wound size. Wounds left uncovered and open to the air develop a layer of eschar, or scab, over the granulation tissue. Although this layer of dried wound exudate and dead cells protects the wound from environmental contamination, it also prevents keratinocyte migration so that reepithelialization cannot occur. Reepithelialization may thus be accelerated by preserving an optimally moist environment.

Collagen repair starts in the proliferative phase and extends into the final remodeling phase. Remodeling of the ECM occurs as granulation tissue is reduced via apoptosis (31). Collagen is constantly being synthesized and degraded in order to gain strength through the reorientation of collagen fibers, as wound tissue approaches full strength (25). Collagen deposition in normal wound healing reaches a maximum by 21 days after the wound is created (27); however, it may take up to 2 years or more for a scar to completely form. If the remodeling process is disrupted, the equilibrium between ECM deposition and degradation is lost, leading to the development of fibrosis and excessive scarring (32). Scar tissue contains fewer cells than normal skin and never achieves the same tensile strength as the original skin it has replaced (27,29).

SITES OF PRESSURE ULCERS

Pressure ulcers can develop in any region of the body where regional risk factors are increased (see “Pressure Ulcer Pathophysiology”), and most frequently develop where soft

tissue coverage over bony prominences is reduced. Common sites of pressure ulcer development will vary depending on the most prevalent posture. For example, bed-bound patients will predominantly be lying supine (Fig. 52-2A); thus, the occiput, sacrum, and heels are the highest risk regions. Mobilized wheelchair users will spend most of the time sitting and the highest risk regions will then be the ischia, sacrum, and heels (Fig. 52-2D).

PRESSURE ULCER PATHOPHYSIOLOGY

The term “pressure ulcer” may be misleading in that it implies that pressure is the only risk factor. In fact, the characteristic tissue breakdown and a subsequent failure to heal are well recognized to be multifactorial processes. For example, there is increasing evidence that shear forces are critically important. Clinical evidence regarding risk factors has been mostly correlative rather than causative (33), although animal models and in-vivo studies are providing further details. It can be useful to consider risk factors broadly as either extrinsic, that is, external to the patient’s body, or intrinsic, that is, within the patient’s body (Table 52-1). Psychosocial factors are complex and probably can be classified as both intrinsic and extrinsic.

TABLE 52.1 Risk Factors in Pressure Ulcer Development	
Extrinsic	Intrinsic
Applied pressure	Muscle atrophy
Surface shear	Impaired nutritional status
Friction	Anemia
Local microenvironment	Impaired vascular status
Psychosocial	Impaired mobility
	Impaired sensation

Thorough consideration of the risk factors is of vital importance because they contribute to the development of treatment and rehabilitation strategies. In general, extrinsic risk factors respond more rapidly to clinical interventions, such as changing the seating system used, but this is not always feasible or easily optimized, for example, intraoperative pressure relief. Changes in clinical status can alter intrinsic factors and increase the risk of pressure ulcer development. For example, urinary incontinence will alter the microenvironment of the skin surface and make it more susceptible to maceration and breakdown.

Given these risk factors, it is not surprising that certain populations are especially prone to pressure ulcer development. These include the elderly with reduced mobility, hospitalized individuals with complex medical conditions, those with cognitive impairments, and those with motor and sensory impairment such as spinal cord injury.

### Pressure

Applied isostatic pressure compresses the soft tissues equally along all axes and causes little or no tissue damage. However, in most real-life situations, applied pressure is not isostatic and the soft tissues will compress along the axes of loading. As applied pressure increases the local capillaries, deeper vasculature will become progressively occluded, impeding blood flow. Lymphatic circulation will be impaired, reducing local drainage of intracellular waste materials and increasing the risk of edema.

The soft tissues can be defined as a composite viscoelastic material, in other words, the response to applied loads varies with the duration of application. Relatively high loads can be tolerated for a short period of time, with complete elastic recovery on removal of the load. Over longer periods of applied load, the viscous nature of the soft tissues predominates, leading to irreversible tissue damage and increased full recovery time for reversible damage. Specific times and magnitudes of critical applied loads vary individually, dependant on the resilience of the local tissues, which is, in turn, dependant on intrinsic factors (34) such as those described in this chapter.

Removal of applied loads after a period of vascular occlusion results in a transient increase in regional blood flow. The duration of this phenomenon, known as reactive hyperemia, is directly related to the preceding duration of occlusion. During the hyperemic phase, tissue damage can occur due to oxygen-free radical activity, which is incompletely buffered in tissue under oxidative stress (35–37). This has led to the proposal that repetitive ischemia/reperfusion injury is a significant pathway to the development of chronic pressure-related wounds. Animal studies have found that repetitive ischemia/reperfusion causes more severe tissue damage than a single, prolonged ischemic insult (38,39). The response to cyclic loading varies for metabolic and myogenic components of skin blood flow, suggesting that optimization of alternating pressure support surfaces requires personalized evaluation of intrinsic blood flow (40).

Many clinicians have observed that patients may appear to have a minor wound or even only some localized discoloration, which then rapidly breaks down to reveal extensive subcutaneous damage, even down to and including the bone. Such wounds are the result of deep tissue injury, that is, tissue breakdown that has its origin in the soft tissues nearer to the bone rather than to the skin surface. Theoretical models using finite element analysis have indicated that peak pressures under applied load occur at the bone-muscle interface (41) and that the magnitude is strongly dependant on the local geometrical and biomechanical characteristics (42). Recent human studies have shown that internal tissue loads are significantly higher in individuals with paraplegia compared to age-matched able-bodied individuals (43), and that postural changes significantly affect these loads. These methods have yet to be applied to other at-risk populations, such as the elderly; however, similarities in tissue biomechanical properties would be predicted.

### Shear and Friction

Shear force is defined generally as a force or a component of force acting parallel to the plane. For a patient, shear forces can originate from nonuniform intrinsic pressure distributions, surface shear, or tangential forces at the body/support interface and cause transverse tissue distortion, that is, shear stresses and strains. Although it has been found that shear force alone does not appear to induce tissue breakdown (44), shear in combination with normal applied pressure will occlude blood vessels at much lower applied forces than normal applied pressure alone (45). Shear strains within the tissue can also disrupt tissue layers. Shear is thus widely considered to be the most important risk factor because blood flow occlusion and tissue damage occurs much more rapidly when shear stresses and strains are present. In recognition of this, the NPUAP convened the “Shear Force Initiative” in 2005 (46). To date, this group has not issued specific guidelines and the direct measurement of shear forces in clinical practice remains challenging.

If shear forces are overcome, slip will occur between the two surfaces. This friction may result in both epidermal abrasion and subepidermal blistering (47,48). Friction alone may not cause pressure ulcers, but in combination with other risk factors such as a compromised microenvironment, it would appear to heighten the risk of rapid tissue damage.

### Immobility

Impaired mobility is commonly due to paralysis or other concurrent medical conditions, leading to an increased risk of pressure ulcer development, especially in the hospital setting (49,50). Motor paralysis will directly affect a person's ability to respond unconsciously to potential noxious stimuli, for example, fidgeting while sitting or turning while asleep. Reduced mobility also profoundly alters the individual's ability to consciously perform postural maneuvers necessary to relieve prolonged applied pressure, from weight shifting while sitting to walking. The loss or reduction of mobility may be further

complicated by sensory impairment, leading to the absence or alteration of normal perception of environmental stimuli such as pain or temperature. Patients with impaired sensation and/or proprioception are at an increased risk of pressure ulcer development because the individual cannot sense the warning signals that precede tissue damage.

### Nutrition

Impaired nutritional status is another significant risk factor for the development of pressure ulcers (51,52). Moreover, the malnourished patient will also have an impaired response to healing. Protein depletion may lead to decreased perfusion and impaired immune response. Low serum protein level may be associated with interstitial edema, leading to decreased tissue elasticity, hence reducing tissue transportation of oxygen and nutrients from the blood to the skin (53). Increased tissue pressure as a result of interstitial edema may decrease blood flow to the skin, thus increasing the risk of pressure ulcer development (54). Furthermore, the presence of an exuding pressure ulcer may cause protein loss and the patient may then develop negative nitrogen balance.

Nutritional status can be measured by various means: food intake, body weight, body mass index (BMI), serum total protein, albumin, and serum prealbumin. Serum total protein level less than 6.4 g/dL has been associated with the development of pressure ulcers (10). Serum albumin level less than 3.5 mg/dL has also been associated with pressure ulcer development (55). Serum prealbumin has a shorter half-life than serum albumin, and therefore, is a more sensitive indicator for measuring nutritional status. The Mini Nutritional Assessment (MNA) and Mini Nutritional Assessment Screening Form have been found to be advantageous in the screening of nutritional status in elderly people with pressure ulcers (56,57). The severity of a pressure ulcer can be directly related to the degree of hypoalbuminemia (58). Fluid balance must also be considered in conjunction with nutritional status since dehydration will decrease the cellular nutrient delivery.

### Local Microenvironment

The local environment at the skin-support interface, termed the microenvironment, has a localized effect on the risk to pressure ulcer development. This umbrella term covers several factors including temperature, moisture, and acidity.

Skin temperature provides an indicator of tissue perfusion. It has been found that immobile patients do not recover preloading skin temperatures after a period of prolonged loading (59). However, elevated body temperatures will raise metabolic activity increasing the need for cellular oxygen. Animal studies have found that deep tissue damage occurs at 10° above room temperature whereas even higher temperatures caused both cutaneous and subdermal damage (60). In some patient populations, such as those with SCI, dysfunctional temperature regulation may produce abnormal variations in microenvironmental temperature.

Moisture from sweat or incontinence will both superhydrate the epidermis and alter the acidity. Skin maceration

will both soften the stratum corneum and increase the friction coefficient of the epidermis. The net effect is rapid destruction of the epidermis and reduced antibacterial functionality (61). Both sweat lactate and urea concentrations become elevated with prolonged ischemia (62, 63), implying that sweat analysis may be a useful predictive indicator of early tissue damage and pressure ulcer development.

### Anemia

Anemia has been identified as a risk factor in both the general (64) and the spinal cord literature (65,66). Hemoglobin level below 12.0 to 14.0 g/dL has been associated with the development of pressure ulcers (67). The literature suggests a correlative relationship, but presumably anemia will lead to impaired delivery of oxygen and nutrients to the local tissue, affecting both the development and the healing of pressure ulcers.

### Impaired Vascular Status

Impaired vascularity of the soft tissues is increasingly recognized as a risk factor for the development of pressure ulcers. Tissue vascularity can be impaired as a result of different pathophysiology, for instance, the impairment of microcirculation due to diabetes mellitus (68), and ischemia to deep tissues as a result of compression or pressure. In fact, there is increasing evidence that deep tissue injury is a significant risk factor in the development of pressure ulcers, especially in conjunction with other risk factors (69). This concept is further discussed elsewhere in this chapter.

### Muscle Atrophy

Muscle atrophy is a common consequence of aging and neuromuscular conditions, such as spinal cord injury and stroke. It may be due to muscle denervation, or simply due to disuse. Individuals with muscle atrophy are particularly at high risk of developing pressure ulcers because it leads to an increase in the interface pressure between the weight-bearing skin areas and the support surfaces. For instance, the gluteal muscles provide cushioning effect between the ischial tuberosity and the seating surface. Gluteal muscle atrophy following spinal cord injury will increase the interface pressure between the ischial skin area and the support surfaces such as the wheelchair cushion or the mattress. When this problem is compounded by other risk factors such as immobility, it puts the individual at high risk of pressure ulcer development.

### Psychosocial/Lifestyle

Some psychosocial factors and lifestyle can be readily addressed by clinicians; however, there is often a need to address non-clinical problems (70). For example, smoking cessation and substance abuse programs can improve the overall physical and mental health. Other issues, such as familial support, access to specialized health care, and independence of community mobility impact social integration. Effective management requires a multidisciplinary team approach.

## RISK FACTOR MEASUREMENT

Many of the risk factors described in the previous section can be evaluated using standard clinical procedures, such as blood work to determine the nutritional status. Quantitative measurement of specific pressure ulcer risk factors, such as interface pressures and blood flow, require more specialized approaches.

### Interface Pressure Mapping

Interface pressure mapping has become more widely used as an assessment tool in wheelchair and seating clinics (71,72). Patients with complex seating needs and those requiring repeated evaluations routinely receive interface pressure assessments as part of the review of both posture and function. Several commercially available systems are reliable, accurate, repeatable, and user-friendly. All these systems include a pressure sensor mat placed between the patient and the support surfaces. This mat is thin and flexible in order to minimize disruption of the interface being measured and contains an array of sensing elements (sensors) that are rapidly scanned to complete a detailed image of the regional pressure distribution. The resulting pressure map is displayed in real-time on a computer screen and provides clinical information, such as location of high pressure points. In addition, real-time pressure maps can be used as biofeedback for patients, who can see the effects of various cushions and weight-shifting maneuvers.

### Blood Flow Measurement

The measurement of interface pressures alone is not sufficient: Maintenance of tissue health requires an adequate supply of nutrients from the blood. Blood flow measurement is thus important for quantitative identification of pressure ulcer risk. Various noninvasive techniques have been used to measure blood flow under applied load.

Transcutaneous blood gas electrodes measure the partial pressure of oxygen and/or carbon dioxide in the skin. Localized heating ensures maximal vasodilation so that capillary blood gas tension is equal to arterial tension. Multisensor systems allow the simultaneous measurement of several at-risk locations. Transcutaneous blood gas measurement has been used in studies to determine both pressure ulcer risk (63,73,74) and healing (75,76).

Laser Doppler flowmetry provides noninvasive measurement of skin blood flow at a depth of about 1 mm via laser and fiber optics technology, and has been used to assess the effects of both prolonged and alternating loading (40,77).

Tissue reflectance spectroscopy utilizes the absorption spectrum of visible light to quantify the blood content and oxygenation of the skin. Sensors have been designed that are suitable for measurements at the support interface (78); however, use is currently mainly in research settings (79,80).

### Soft Tissue Imaging

The use of soft tissue imaging to identify pressure ulcer risk and/or measure pressure ulcers has mostly been limited to research

studies. Both CT and MRI can show deep tissue damage (81,82) but are limited in clinical applicability. High frequency ultrasound has been reported to show specific progression of pressure ulcer development (83); however, it would appear that a significant level of expertise is required for reliable interpretation.

## ASSESSMENT

Scales have been developed to provide clinicians with structured tools for pressure ulcer risk assessment and wound healing evaluation. These scales assign ordinal values to multiple qualitative and quantitative measures. Thresholds are defined that determine a positive or negative outcome, that is, high risk/low risk or healing/nonhealing.

### Pressure Ulcer Risk Assessment Scales

Risk assessment scales are designed to be broadly applicable to patients with varying diagnoses in any health care setting. The goal is to provide a readily useable tool to identify patients needing preventative interventions so that limited resources can be most effectively allocated. Even the most streamlined tool requires some degree of observer training.

The three most widely used scales are the Braden (84), Norton (85), and Waterlow (86) scales. Of these, the Braden scale has been most widely used and validated in several different settings (87–89), although it is not always recommended as the optimal tool for clinical management, particularly in acute care settings (90,91). There are marked differences between these scales (92) and it should be borne in mind that subscales cannot necessarily be used independently with the same validity. Modifications of scales for specific settings may improve the predictive value at a particular location (93), but testing and observer training is required for widespread implementation.

The use of a pressure ulcer risk assessment scale should not override all clinical judgement; specific patient factors may affect risk in ways not captured by a scale and must always be considered in an individual plan of care.

### Staging

The intent of staging is to provide an objective description of the severity of the pressure ulcers. Up until 2007, there had been multiple proposed systems, but the most accepted one was the four-stage system proposed by the NPUAP in 1989 (94). The NPUAP system was based on the layers of the tissues involved. It was derived from the staging system proposed by Shea in 1975 (95). Subsequently, it was revised in 1997 to specifically address the description of Stage I ulcers so that variables such as skin tone, temperature, and tissue consistency would be addressed. The NPUAP staging system has been endorsed by the Wound Ostomy & Continence Nurses Society (WOCN) and the Agency for Health Care Policy & Research (AHCPR) (96). The NPUAP staging system was not meant to be used for other skin wounds, such as diabetic foot ulcer, or arterial ulcers. It must be noted that the staging system is not based on the

natural history of pressure ulcer development. The four stages described are not necessarily based on histopathology or the progression of the pressure ulcers. This widely adopted staging system was revised in 2007. In order to understand the changes in the new system and the rationale behind the changes, it is important to compare the two systems (Table 52-2).

As the pressure ulcer improves, the depth and size may decrease. However, it is not appropriate to “reverse stage” (97) the ulcer, because the staging system was not designed to indicate the healing process. This would lead to the assumption that full thickness pressure ulcers heal by replacing the same structural layers of tissues that were lost during the development of the pressure ulcer. As full thickness pressure ulcers heal and become shallower in depth, they do not replace lost muscle, subcutaneous fat, and dermis before they reepithelialize. Rather, the defect is filled with granulation tissue of a rather different composition (endothelial cells, collagen, fibroblasts, and ECM). Therefore, it would be inaccurate and misleading to describe a healing Stage IV ulcer to become Stage III, then Stage II as it starts to heal and become less deep. It is appropriate to describe a “healing Stage IV ulcer” with the accurate size, depth, and description of the other wound characteristics, as one should do with the comprehensive assessment of any pressure ulcer.

### Pressure Ulcer Healing Evaluation Scales

Several wound evaluation tools have been developed that combine qualitative assessment of wound status with wound size measurement. These include the Pressure Ulcer Scale for Healing (PUSH) (98,99), the Pressure Sore Status Tool (PSST) (100), and the Leg Ulcer Measurement Tool (LUMT) (101). Observer training is necessary for reliable implementation of these tools. Qualitative measures may have high interobserver variability, due to subjective biases.

The PUSH tool is the most extensively validated tool for assessment of pressure ulcer healing in clinical settings (102,103). Wound size, defined as surface area, is the predominant factor in this tool. Careful wound size measurement is essential to maintain the overall accuracy, particularly for repeated measures over extended time periods. A recent survey found that the PUSH tool is generally considered to be reliable and easy to use, although respondents were less positive regarding its usefulness (104).

### Wound Measurement

In order to evaluate and monitor the progress of a pressure ulcer over time, accurate wound measurement is essential. Linear measurements of length (maximum length measured in the axis from head to toe), width (maximum width perpendicular to the length), and depth are commonly used in clinical practice. However, they may not be the ideal measurement method for pressure ulcers that can be rather large, deep, and irregular in size and shape (105). Needless to say, linear measurements may be operator-dependent and have low inter-rater reliability. Therefore, alternative wound measurement methods that provide high accuracy and good inter-rater reliability are

needed. Digital wound measurement devices can potentially satisfy these criteria.

Two digital imaging techniques that have been introduced for clinical use are planimetry and digital image analysis technique, photogrammetry. Planimetry measures the surface area of a pressure ulcer by tracing its boundary, with the traced area digitally calculated by a computerized device (e.g., The Visitrak system, Smith & Nephew, Largo, FL, USA), whereas photogrammetry utilizes digital photography of the pressure ulcer to measure its surface area (e.g., The VeV MD, Verge Videometer Measurement Documentation system, Vistamedical, Manitoba, Canada). Both digital techniques were shown to have higher accuracy than linear measurement (106,107). However, their clinical applicability may be limited by their cost and the increased time needed to produce the measurements. Furthermore, they still do not measure wound volume, which is the most accurate measurement for pressure ulcers. All of these factors should be considered when deciding which measurement method is to be used.

## PRINCIPLES OF TREATMENT

The treatment of pressure ulcers is a complex process. It starts with the prevention of their development. This includes the identification, and subsequently the correction of risk factors, as discussed above. Then specific treatment of a pressure ulcer aims to correct the local wound environment, in order to provide the most optimal condition for healing. This includes the selection of appropriate dressings, management of the wound bed, use of specific modalities to promote wound healing, as well as the specific methods of pressure relief. As a general rule, conservative management is the first line of treatment, with surgical intervention being considered after adequate conservative treatment fails in Stage III or IV pressure ulcers.

There are multiple, comprehensive, practical guidelines on the management of pressure ulcers, including the guidelines by the Wound, Ostomy and Continence Nurses Society (108), the Consortium for Spinal Cord Medicine (109), the AHCPR (96), the Registered Nurses Association of Ontario (110), and the Royal College of Nursing (111), to name but a few. The goal of this section is to provide the principles and scientific basis of the overall management of pressure ulcers.

### Medical Treatment of Underlying Systemic Factors

The management of the intrinsic and extrinsic risk factors is crucial in both the prevention and treatment of pressure ulcers. Correction of some of the stated risk factors is self-evident and will not be discussed in this section. We will, therefore, focus on specific risk factors that require further discussion.

### Nutrition

The management of nutrition has been widely recognized as an essential part of pressure ulcer prevention and management,

**TABLE 52.2 Comparison of NPUAP Staging Systems (1989 and 2007)**

NPUAP Staging System (1989)	2007 Revision
<p><i>Stage I:</i> An observable pressure-related alteration of intact skin whose indicators as compared to the adjacent or opposite area on the body may include changes in one or more of the following: skin temperature (warmth or coolness), tissue consistency (firm or boggy feel), and/or sensation (pain, itching). The ulcer appears as a defined area of persistent redness in lightly pigmented skin, whereas in darker skin tones, the ulcer may appear with persistent red, blue, or purple hues.</p> <p><i>Stage II:</i> Partial thickness skin loss involving epidermis, dermis, or both. The ulcer is superficial and presents clinically as an abrasion, blister, or shallow crater.</p> <p><i>Stage III:</i> Full thickness skin loss involving damage to, or necrosis of, subcutaneous tissue that may extend down to, but not through, underlying fascia. The ulcer presents clinically as a deep crater with or without undermining of adjacent tissue.</p> <p><i>Stage IV:</i> Full thickness skin loss with extensive destruction, tissue necrosis, or damage to muscle, bone, or supporting structures (e.g., tendon, joint capsule). Undermining and sinus tracts also may be associated with Stage IV pressure ulcers.</p>	<p><i>Suspected Deep Tissue Injury:</i> Purple or maroon localized area of discolored intact skin or blood-filled blister due to damage of underlying soft tissue from pressure and/or shear. The area may be preceded by tissue that is painful, firm, mushy, boggy, warmer, or cooler as compared to adjacent tissue.</p> <p><i>Further description:</i> Deep tissue injury may be difficult to detect in individuals with dark skin tones. Evolution may include a thin blister over a dark wound bed. The wound may further evolve and become covered by thin eschar. Evolution may be rapid, exposing additional layers of tissue even with optimal treatment.</p> <p><i>Stage I:</i> Intact skin with nonblanchable redness of a localized area usually over a bony prominence. Darkly pigmented skin may not have visible blanching; its color may differ from the surrounding area.</p> <p><i>Further description:</i> The area may be painful, firm, soft, warmer, or cooler as compared to adjacent tissue. Stage I may be difficult to detect in individuals with dark skin tones. May indicate “at-risk” persons (a heralding sign of risk).</p> <p><i>Stage II:</i> Partial thickness loss of dermis presenting as a shallow open ulcer with a red pink wound bed, without slough. May also present as an intact or open/ruptured serum-filled blister.</p> <p><i>Further description:</i> Presents as a shiny or dry shallow ulcer without slough or bruising.<sup>a</sup> This stage should not be used to describe skin tears, tape burns, perineal dermatitis, maceration, or excoriation.</p> <p><i>Stage III:</i> Full thickness tissue loss. Subcutaneous fat may be visible but bone, tendon, or muscle are not exposed. Slough may be present but does not obscure the depth of tissue loss. May include undermining and tunneling.</p> <p><i>Further description:</i> The depth of a Stage III pressure ulcer varies by anatomical location. The bridge of the nose, ear, occiput, and malleolus do not have subcutaneous tissue and Stage III ulcers can be shallow. In contrast, areas of significant adiposity can develop extremely deep Stage III pressure ulcers. Bone/tendon is not visible or directly palpable.</p> <p><i>Stage IV:</i> Full thickness tissue loss with exposed bone, tendon, or muscle. Slough or eschar may be present on some parts of the wound bed. Often include undermining and tunneling.</p> <p><i>Further description:</i> The depth of a Stage IV pressure ulcer varies by anatomical location. The bridge of the nose, ear, occiput, and malleolus do not have subcutaneous tissue and these ulcers can be shallow. Stage IV ulcers can extend into muscle and/or supporting structures (e.g., fascia, tendon, or joint capsule), making osteomyelitis possible. Exposed bone/tendon is visible or directly palpable.</p>

**TABLE 52.2 Comparison of NPUAP Staging Systems (1989 and 2007) (Continued)**

NPUAP Staging System (1989)	2007 Revision
	<p><i>Unstageable:</i> Full thickness tissue loss in which the base of the ulcer is covered by slough (yellow, tan, gray, green, or brown) and/or eschar (tan, brown, or black) in the wound bed.</p> <p><i>Further description:</i> Until enough slough and/or eschar is removed to expose the base of the wound, the true depth, and therefore stage, cannot be determined. Stable (dry, adherent, intact without erythema or fluctuance) eschar on the heels serves as “the body’s natural (biological) cover” and should not be removed.</p>

<sup>a</sup>Bruising indicates suspected deep tissue injury.

with a focus on protein and micronutrients such as vitamins and amino acids. Dietary protein is very important in the healing of pressure ulcers in malnourished patients (112). It has been suggested that the need for protein is often underestimated in those with wounds (113). The AHCPR guidelines recommend that individuals without a pressure ulcer should take 1.0 to 1.25 g/kg of body weight/day of protein, while those with a pressure ulcer should take 1.25 to 1.5 g/kg/day. The Consortium of Spinal Cord Medicine (109) guidelines recommend 1.2 to 1.5 g/kg/day for those with a Stage II pressure ulcer, and 1.5 to 2.0 g/kg/day for those with a Stage III or Stage IV pressure ulcer. It must be noted that the nutritional needs should be adjusted according to the presence of any medical comorbidity.

The role of micronutrients such as vitamin A, C, E, zinc, and arginine in the treatment of pressure ulcers is less clear. Arginine is a nonessential amino acid. It has been shown to enhance the wound strength and collagen deposition in both the human and rodent models, with artificial incisional wounds (114). L-Arginine is the only substrate for nitric oxide synthesis. In diabetes mellitus, there is a decrease in nitric oxide at the wound site, and this is accompanied by impaired healing. In the diabetic rat model, the supplementation of L-arginine has been shown to improve wound healing with increased nitric oxide synthesis (115). Though some research trials have demonstrated that the use of vitamin C, zinc, and arginine may be helpful in the treatment of pressure ulcers (116,117), further randomized, controlled trials with larger sample size are needed to confirm these findings (118,119).

### Impaired Mobility

Impaired mobility is a significant problem in those with neuromuscular weakness and in postsurgical patients whose mobility may be temporarily impaired. It is a constant risk factor as the patient has unrelieved pressure from immobility whether s/he is sitting or lying down. Pressure relief for both the prevention and treatment of pressure ulcers is of critical importance to this at-risk population. When at-risk individuals are in bed, many guidelines recommend turning every 2 hours, even when a turning mattress is being used. It is important to pay attention

to specific pressure-bearing areas, such as the sacrum, ischial tuberosity, trochanter, and the heels. Turning from side to side will relieve pressure over the sacrum and ischial tuberosities, but the patient should not be turned all the way to the side or the trochanteric areas will be under high pressure. The heels can be suspended by placing pillows under the lower extremities, or by the use of orthoses that take pressure off the heels. Caregivers and patients should be educated about the importance of turning. Research is needed to determine the optimal turning frequency (120). For individuals in the sitting position, current guidelines recommend pressure relief every 15 minutes.

## WOUND CARE

The purpose of local wound care is to provide the wound with the most optimal environment for healing. Specific factors that need to be taken into consideration are:

*Level of moisture:* the provision of a moist healing environment has been accepted to be the standard of care in pressure ulcer management. It is believed that wound healing is optimized at an appropriately moist environment, while a dry or excessively moist environment will be detrimental to wound healing. Depending on the pre-existing level of moisture in the wound bed, various dressings can be used to correct the level of moisture in the wound (121). The different types of dressings are discussed under *GENERAL DRESSING GUIDELINES*.

*Debridement of necrotic tissues:* the removal of necrotic tissues, eschar, and slough is a well-accepted practice in wound bed preparation for healing. These devitalized tissues may support the proliferation of pathogens. Though debridement is widely practiced, there has not been any substantial research study on this topic. There are four methods by which debridement can be achieved (122). In the order of their onset of action, with the most rapid onset being first, they are: sharp debridement with scalpel or scissors, nonselective mechanical debridement through the use of irrigation or a wet-to-dry dressing, chemical debridement through the use of an enzyme such as collagenase without damage to the granulation tissues, and

autolytic debridement. Whenever possible, sharp debridement is the method of choice as it provides the most effective way to remove any necrotic tissue from the wound, though it must be noted that the NPUAP advises against the debridement of eschar in the heel (1,97). Sharp debridement requires the skills of an experienced clinician and sometimes the necrotic materials may be too adherent at the wound base for successful sharp debridement. In such cases, mechanical and chemical debridement would be more appropriate, though it takes longer to achieve the desired effect.

**Wound cleansing:** wound cleansing facilitates the removal of necrotic materials, exudates any metabolic wastes away from the wound, thus promoting wound healing (96). It also may decrease the bacterial load in the wound tissue; this is important because a bacterial count of greater than  $10^5$  may be associated with the development of wound infection (123). Wound irrigation at a pressure of 4 to 15 psi (pounds per square inch) is recommended (124). Below 4 psi, the irrigation pressure may not be effective but above 15 psi, the pressure may potentially drive the wound bacteria into the blood, increasing the risk of bacteremia. Irrigation devices that deliver a pressure above 8 psi, such as a 35 mL syringe with a 19-gauge needle or angiocatheter, are thought to be more effective. The use of a bulb syringe will produce a lower irrigation pressure, and is thus less effective. Hydrotherapy with whirlpool or pulsatile lavage is effective for wound cleansing and will be discussed under *ADJUVANT THERAPIES*. Antiseptic solutions are not recommended for wound cleansing because of their cytotoxic properties, which may impair wound healing. Normal saline is the irrigant of choice.

**Protection of wounds:** this can be achieved by the use of an appropriate dressing to protect the wound from external factors such as further trauma, and bacterial or chemical exposure.

## GENERAL DRESSING GUIDELINES

Dressings provide a physical barrier that protect the wounds, help optimize the moisture level in the local wound microenvironment, assist in autolytic debridement, and can also be used as a medium to deliver topical medication to the wound. The following factors need to be considered when selecting a dressing:

- Does the dressing provide sufficient physical barrier for protection from the environment?
- Is there necrotic material in the wound? If so, is autolytic, enzymatic, or mechanical debridement most appropriate?
- What is the moisture level in the wound? Is drainage control or moisture retention the goal?
- Is there a suspicion of bacterial overload in the wound bed, for example, strong odor, excessive drainage? All pressure ulcers will have some degree of colonization but this does not necessarily mean that the wound is infected. Is an antimicrobial topical agent necessary?
- The frequency of change and ease of application of the dressing.
- The availability and cost of the dressing to the patient.

It is important to recognize that the pressure ulcer healing process is dynamic and therefore, the wound tissue condition needs to be assessed continuously with appropriate adjustment of the dressing choice.

The huge number of commercially available dressings can be helpful and yet overwhelming to the clinician. It is more helpful to understand the principles and mechanisms of action of the different types of dressings, than to know the various products by name. Table 52-3 describes the classes of the available dressings. Topical agents such as enzymatic debridement agents and antimicrobial agents may be used in conjunction with some of these dressings. Though growth factor gel, for example, bcraplermin, has been used for the treatment of diabetic foot ulcers, it has not been indicated for pressure ulcer treatment.

## Adjuvant Therapeutic Modalities

There are many therapeutic modalities used in the treatment of pressure ulcers, including electrical stimulation (ES), hyperbaric oxygen, infrared, ultraviolet, low-energy laser irradiation, and ultrasound. The AHCPR Guidelines (96) supported only the use of hydrotherapy for the cleansing of the ulcers and ES for nonhealing Stage III and IV pressure ulcers. This section will examine these recommended modalities, and some newer, but commonly used therapeutic modalities.

### Hydrotherapy—Whirlpool and Pulsatile Lavage Therapy

Hydrotherapy is particularly helpful for cleansing and mechanical debridement of Stage III and IV wounds. Conventionally, hydrotherapy for pressure ulcer management has been carried out through the use of a whirlpool. Despite its clinical efficacy (125), whirlpool therapy has been found to have some clinical and practical limitations, including cross-contamination between patients, pseudomonas infections (126), and potential skin infections for caregivers who are in contact with the contaminated water.

Pulsatile lavage therapy is a different form of hydrotherapy that encompasses all of the advantages of whirlpool therapy, but without the potential adverse effects. A portable device is used that delivers pulsed jet streams of water at a known, preset pressure, which is compliant with the pressure range (4–15 psi) recommended for wound cleansing (127). The potential for cross-contamination between patients is eliminated because the device is for single-patient use, and is carried out by a caregiver in the patient's room. Furthermore, pulsatile lavage therapy is less labor intensive than whirlpool hydrotherapy because it does not involve any patient transfer and there is no decontamination of equipment afterwards. Pulsatile lavage appears to be a preferred alternative to whirlpool therapy in the management of pressure ulcers. The clinical efficacy of pulsatile lavage in the treatment of pressure ulcers is under investigation.

### Electrical Stimulation

ES has been used for the treatment of chronic wounds for many years (128) and has been specifically recommended for

**TABLE 52.3** Classes of Available Dressings

Class of Dressing	Pressure Ulcer Indication	Mechanisms of Action	Potential Adverse Effect
<i>Gauze</i> Dry dressing Wet-to-dry  Wet-to-moist	Scabbed over wounds Stage III, IV pressure ulcers with necrotic materials Stage III, IV pressure ulcers	Physical barrier Mechanical debridement, absorbent Provide moist healing environment	Nonselective, may remove granulation tissue May dry out and turn into wet-to-dry dressing
<i>Occlusive</i> —transparent film dressings that are semi-permeable	Stage I, II pressure ulcers with no drainage	Physical barrier, moisture retention, promote autolytic debridement	Excessive moisture retention if wound drains excessively
<i>Gel</i> —hydrophilic polymer that comes in sheet, granules, or liquid gel forms	Stage II, III, IV pressure ulcers with no to little drainage	Provide moist healing environment, promote autolytic debridement	Too much exudate from wounds may cause excessive moisture
<i>Hydrocolloid</i> —dressings containing gel-forming agents (e.g., sodium carboxymethyl-cellulose and gelatin), often combined with elastomers and adhesives, and applied to a carrier	Stage II (III) pressure ulcers with little drainage	Occlusive and adhesive wafer dressing that forms a gel-like substance with wound exudate, promoting moist healing and autolytic debridement	Too much exudate from wounds may cause excessive moisture; may crease or roll up and create pressure to wounds
<i>Foam</i> —polyurethane dressing that comes in sheets or fillers	Stage II, III, IV pressure ulcers with little to great drainage	Provide moist healing environment, promote autolytic debridement	Too much exudate from wounds may cause excessive moisture
<i>Alginates</i> —highly absorbent, biodegradable dressings derived from seaweed	Stage III, IV pressure ulcers with moderate-to-great drainage	Absorb excessive exudates, promote autolytic debridement	May cause foreign body reaction
<i>Matrix</i> —collagen matrix that provides three-dimensional scaffolding, attracts host cells and tissue remodeling	Stage III, IV pressure ulcers	Promote granulation and epithelialization into the matrix	

the treatment of severe (Grade III or IV) pressure ulcers by the AHCPR Clinical Practice Guidelines. There have been many clinical reports of the technique. Three separate meta-analyses (129–131) have attempted to consolidate the many varying clinical reports on the success of this technique (132–134). All these reports considered ES to be an effective modality; however, the specific treatment and stimulation paradigms employed were found to be highly variable. The mechanisms by which ES promotes wound healing are not fully understood, leading to a need to optimize delivery of treatment.

### Negative Pressure Wound Therapy

Negative pressure wound therapy (NPWT) is based on the theory that the negative pressure facilitates drainage of wound exudates and enhances wound healing through a number of mechanisms (135). More specifically, NPWT is proposed to decrease the bacterial load and edema while concurrently promoting an improved local circulation and increasing granulation. NPWT devices consist of a suction pump with foam and occlusive dressing to create negative pressure on the wound being treated. Despite the lack of official guidelines on the use of NPWT, it has been widely used in clinical practice

and there have been consensus reports (136,137). The primary recommendations are that NPWT is indicated when the following clinical criteria are met:

- Anatomical surfaces that allow a tight seal
- Adequately prepared wounds, for example, debrided, free of eschar, and necrotic materials
- Wound drainage
- Patient compliance

NPWT is contraindicated when wounds are dry, there is uncontrolled pain, untreated infection, malnutrition, or poor hemostasis.

Effective NPWT will produce a response within 2 to 4 weeks. Discontinuation is recommended if there is less than 30% wound size reduction after 4 weeks.

Despite its popularity, none of the major clinical reviews and guidelines have found sufficient scientific evidence to support the use of NPWT for wound healing (138–141). There were too few randomized controlled trials. Small sample size and poor study design limit the validity of existing studies. Further research is needed to determine the utility of NPWT as a treatment modality for appropriate nonhealing pressure ulcers.

### Therapeutic Ultrasound

Therapeutic ultrasound is a deep heating modality that is commonly used for pressure ulcer healing. Its deep heating property is theorized to improve the vascularity of the wound tissues, thus improving healing. However, there is only limited evidence from clinical trials (142).

### Electromagnetic Therapy

There is growing interest in the use of electromagnetic therapy for the treatment of pressure ulcers. This modality has been shown to increase the blood flow, collagen formation, and also granulocyte infiltration in both in vitro and animal models to induce healing (143). However, clinical trial evidence is again lacking.

## PROVISION OF APPROPRIATE SEATING SYSTEMS AND MATTRESSES

Appropriate seating systems and mattresses for at-risk patients must primarily reduce the risk of pressure ulcer development. Depending on the specific patient condition and health care setting, other factors must also be considered such as postural control, optimization of independent function and, when applicable, availability of assistance and care. There are many different types of support surfaces available. General guidelines for prescription are of value, but it remains important to assess each patient individually. The provision of support surfaces should be reviewed regularly for at-risk patients, both in the short-term acute care setting and in longer term care. Changes in overall health and other risk factors frequently change a patient's requirements for effective pressure relief.

### Seating Systems

Along with the provision of an appropriate wheelchair, an effective cushion is essential in order to provide a seating system that will maximize the function and minimize the risk for pressure ulcer development. There are a wide and continuously increasing range of pressure relief cushions available. The main classes of pressure relief cushions available are summarized in Table 52-4. Some cushions will combine two or more classes of material in order to achieve improved pressure relief properties, in combination with postural stability. USA TechGuide is an online resource maintained by the United Spinal Association that provides complete and constantly updated reviews of currently

available pressure relief cushions (144). Donut-rings should never be used as pressure relief cushions because, although pressure is relieved at the center of the ring, pressure distribution around the perimeter leads to high regional pressures and blood flow occlusion, thus exacerbating the overall risk.

### Pressure Relief Mattresses

Pressure relief mattresses use many of the same materials as pressure relief cushions. Static and dynamic support mattresses are routinely available. Static support mattresses are appropriate for patients without a pressure ulcer or who can be positioned so that no load is applied to the pressure ulcer at any time. Dynamic mattresses include low air loss mattresses and air-fluidized beds, and are frequently only used for patients with existing pressure ulcers, due primarily to high usage costs. However, all immobile patients are at an increased risk of pressure ulcer development and the recommended 2-hourly turning schedule for pressure relief sometimes poses a staffing challenge. If loading over an existing pressure ulcer cannot be avoided at all times then a dynamic support mattress should be used. The medico-legal repercussions of a patient developing a nosocomial pressure ulcer have led to an increased consideration of use of dynamic support mattresses in many health care facilities (145–147), and it may also be cost-effective (148).

## SPECIALIZED CLINICS

Specialized clinics for patients at-risk for pressure ulcers can include both wheelchair clinics and wound care clinics. The personnel involved in these clinics will vary slightly but a common focus is the prevention and treatment of pressure ulcers.

The wheelchair clinic team generally includes a physiatrist, a physical and/or occupational therapist, and a medical engineer. The physiatrist plays a critically important role in ensuring that the overall risk factor status is considered and that comorbidities, such as nutritional status, are addressed. It is valuable for at least one of the team members to have completed an appropriate Rehabilitation Engineering and Assistive Technology Society of North America (RESNA) accreditation program (149). Certification as an Assistive Technology Practitioner (ATP) is for professionals who assess patients and assist in system selection and user training. In the wheelchair clinic, the therapist or ATP activities will include

**TABLE 52.4** Cushion Material Characteristics

Material	Pressure Relief	Postural Control	Approximate Lifetime (y)	Cost	Cost Effectiveness
Foam	Poor–medium	Medium–good	0.5–1.0	\$	Poor
Viscoelastic foam	Poor–good	Good	1.0–2.0	\$–\$\$	Medium
Gel	Good	Good	3.0–5.0	\$\$–\$\$\$	Good
Flotation (water or air)	Excellent	Poor	4.0–5.0	\$\$\$	Good

pressure mapping together with assessment of both posture and function. The evaluations will provide the basis for a systematic approach to the selection of a wheelchair/cushion seating system. The Rehabilitation Engineering Technologist (RET) certification is for those who are involved with wheelchair modifications and customization. In the wheelchair clinic, the medical engineer or RET can provide specialized wheelchair controllers and other customized wheelchair components. Initial rehabilitation and follow-up appointments for at-risk patients in a wheelchair clinic can provide an opportunity for continued education of the patient and caregivers, and have been found to lead to a decreased incidence of pressure ulcer development in high-risk patients (150–152).

The focus of the wound care clinic is the effective treatment of patients who have already developed pressure ulcers. The wound care clinic team generally includes a certified wound care nurse, a nutritionist, and a physician. Clinic activities include regular systematic wound evaluation and documentation, using objective measurement tools and standardized procedures. This approach allows defined treatment protocols to be established and has been found to reduce wound healing time, and decrease the incidence of nosocomial pressure ulcers (153).

## SURGICAL MANAGEMENT OF PRESSURE ULCERS

Surgical procedures may be used to treat pressure ulcers. They include: direct closure, skin grafting, skin flaps, musculocutaneous flaps, and free flaps (96). Though there are no clear criteria or clinical practice guideline for the indication of surgical intervention, patients with nonhealing Stage III or IV pressure ulcers despite optimal conservative care, and those with underlying osteomyelitis requiring debridement of the infected bone, may be candidates for surgery. Surgical removal of a bony prominence such as ischiectomy is contraindicated due to poor pressure distribution and postural control postoperatively (154). Risk factors that impair wound healing should be controlled before surgery is considered, including malnutrition, anemia, spasticity, urinary tract infection, incontinence, smoking, and psychosocial issues. It is imperative to provide postoperative pressure relief to the surgical site with appropriate positioning of the patients and pressure-relieving mattresses. As the long-term outcomes of pressure ulcer surgery remain unclear (155,156), careful selection of surgical candidates is of utmost importance.

## NEW CONCEPTS IN PRESSURE ULCER CARE

### Minimizing Bedrest for Pressure Ulcer Treatment

Prolonged bedrest can lead to many complications, thus effective clinical management without bedrest for patients with pressure ulcers is desirable. Prone trolleys allow patients to gain some mobility but provide only limited function and mobility in the community environment. Standing wheelchairs have recently become an increasingly popular option

although they remain expensive. These systems can provide full, extended pressure relief over pelvic region wounds, thus allowing remobilization of individuals with existing pressure ulcers. Standing wheelchairs also have multiple systemic health benefits including increases in lower extremity range of motion, upper extremity strength, bladder, and other systemic functions together with decreased spasm and pain (157). USA Tech-Guide currently lists over 15 power-standing wheelchairs and 11 manual-standing wheelchairs (158,159).

Dynamic wheelchairs and cushions provide an alternative approach to a full standing wheelchair. A dynamic configuration wheelchair varies individual system components in order to relieve pressure over areas of tissue breakdown (160). Dynamic wheelchair cushions provide a means to provide automatic weight-shifting due to cyclic inflation and deflation of air cells in high-load regions and may provide benefits similar to those achieved using an advanced wheelchair system.

Further research is needed to determine the relative merits of advanced wheelchairs and wheelchair cushions for both pressure ulcer prevention and treatment.

### Gluteal Neuromuscular Electrical Stimulation System

Regular use of ES for functional applications can produce changes in regularly stimulated muscles that may increase the health of the muscle and surrounding soft tissues (161,162). Bogie et al. have investigated the use of a 4-channel gluteal electrical stimulation system (GSTIM), specifically designed to decrease risk factors associated with pressure ulcer development for individuals with SCI (163). It was found that subjects who received a GSTIM system showed statistically significant decreases in ischial region pressure over time, together with increased gluteal cross-sectional area and enhanced regional blood flow (164). Dynamic weight shifting produced by the GSTIM system varies seated posture and pressure distributions at the seating interface and augments the efficacy of conventional pressure relief maneuvers.

## SUMMARY

Pressure ulcers remain a major complication for many rehabilitation patients with impaired mobility. Our understanding of the pathophysiology of tissue breakdown and the impact of concurrent systemic risk factors has increased. Advances in therapeutic modalities and standardization of clinical care contribute to the success of rehabilitation practice.

V

# Special Populations

# Sports Medicine

Physiatric involvement in the field of sports medicine has greatly increased over the past two decades. More and more physical medicine and rehabilitation specialists are serving as team physicians at the high school, collegiate, Olympic, and professional levels. In addition, there has been increased involvement in the American College of Sports Medicine as participants and presenters. The Physiatric Association of Sports, Spine and Occupational Rehabilitation continues to promote and actively participate in educational programs dealing with sport medicine. It is encouraging that more physiatrists are publishing articles related to sports medicine, thus increasing Physical Medicine and Rehabilitation's contribution to the literature. Validation of the effectiveness of non-operative treatment of various sports injuries will continue to substantiate the role of physiatrists as leaders in the area of sports medicine.

The primary purpose of this chapter is to review selected concepts pertaining to the treatment of sports injuries. The evaluation and treatment of some common injuries are also presented. Overuse injuries are discussed in a separate chapter in this textbook. The reader should understand that the area of sports medicine is broad; therefore, for those interested in treating sports injuries, additional reading of current textbooks and journals is essential. In addition, clinical experience gained through preparticipation physical examinations, sports clinics, and on-field coverage is invaluable to anyone who desires to care for injured athletes.

Since the previous edition of this book was published in 2005, a team physician consensus statement was developed. In a collaborative effort by six professional organizations—American Academy of Family Physicians, American Academy of Orthopedic Surgeons, American Academy of Sports Medicine, American Medical Society for Sports medicine, American Orthopedic Society for Sports Medicine, and American Osteopathic Academy of Sports Medicine—a consensus statement was devised that outlined the most important elements of sports medicine and their specific issues in injury and illness prevention (1). This chapter addresses every topic discussed in that consensus statement, and thus it is completely up to date in its information at the time of this meeting. Much of the previous edition was left intact, and new contributions have been included on the subjects of cardiovascular issues in sports and on anterior cruciate ligament (ACL) injury prevention.

## TEAM APPROACH TO THE INJURED ATHLETE

Various health care professionals are involved in the care of injured athletes. Medical specialties traditionally involved in the care of athletes include physiatry, orthopedic surgery, internal medicine, family practice, emergency medicine, and pediatrics. Additional important team members include podiatrists, athletic trainers, therapists, nutritionists, and strength and conditioning specialists. The concept of working within a team approach is inherent in physiatry. During residency training and in practice, physiatrists continually coordinate care by interacting with physical therapists, occupational and speech therapists, psychologists, and other pertinent individuals. Although the vast majority of athlete symptoms are musculoskeletal in nature, a variety of problems can arise, ranging from skin disorders to cardiac symptoms. In addition, most acute injuries do not require operative intervention. A well-trained physiatrist would appear to be the most logical choice to direct the sports medicine team, addressing the majority of the nonoperative injuries in conjunction with athletic trainers, therapists, and others, and referring other conditions as needed to the most appropriate specialist in a timely manner.

## BASIC TISSUE PHYSIOLOGY

### Skeletal Muscle

Muscle constitutes the largest tissue mass in the body, comprising 40% to 45% of the total body weight. Muscles originate either from bone or dense connective tissue and are connected to these tissues by either the muscle itself or associated tendons. The muscle-tendon unit will cross one or more joints to its site of insertion, typically on bone. Those muscles that cross one joint are usually located close to bone and are generally involved in postural activities. One-joint muscles possess a slower contraction speed with increased force production. Examples of one-joint muscles include the vastus medialis/lateralis/intermedius of the quadriceps group and the soleus. In contrast to the one-joint muscles, those muscles that cross two or more joints are located more superficially and exhibit faster contraction speeds with relatively reduced force production. Examples of two-joint muscles include the biceps brachii and the gastrocnemius. Muscles can generate and attenuate force on a limb and stabilize a joint when firing synergistically with larger muscles.

Muscle that is torn has a limited ability to regenerate and often heals by dense scar formation. It has been reported that aging muscle demonstrates a decrease in size, number of muscle fibers (type II), and the number of motor units (alpha motor neuron and the muscle fibers it innervates). There is, however, no decrease in metabolic potential for aerobic and anaerobic activities with aging (2). Petrofsky and Lind (3) demonstrated little change in mean handgrip in men aged 22 to 62 years. Vandervoort and McComas found little change in dorsiflexion and plantar flexion torques between men aged 20 to 60 years, with a marked reduction in strength from age 60 to 100 years (4). Frontera (5) strength-trained men between 60 and 70 years and showed 107% and 226% strength increase for knee flexors and extensors. Fiatarone et al. (6) strength-trained nonagenarians, which resulted in a 174% increase in quadriceps strength and a 48% increase in gait speed. These studies demonstrate that muscular strength can be retained until very late in life, thereby supporting the concept that muscle loss with aging is primarily due to disuse more than age-related muscle fiber loss.

### Tendons

As previously mentioned, a tendon is the structure that connects muscle to bone. Tendons consist of dense, regularly arranged collagen fibers meshed with elastin and a proteoglycan/glycosaminoglycan ground substance. The primary function of the tendon is to transmit the force generated in muscle to the bone. This process allows for the generation of movement of the extremities. The tendon is surrounded by a glistening, synovial-like membrane called the epitenon. The epitenon is continuous on its inner surface with the endotenon, a thin layer of connective tissue that contains lymphatics, blood vessels, and nerves. In some tendons, the epitenon is surrounded by a loose connective tissue called the paratenon. The paratenon functions as an elastic sheath that permits free movement of the tendon against surrounding tissue. The blood supply of tendons is variable and is compromised at sites of friction, torsion, or compression. Tendons with a blood supply that is frequently compromised include the supraspinatus, Achilles, and tibialis posterior. Tendons subjected to large, repetitive stresses can tear, become inflamed, or degenerate.

The aging process is associated with an increase in collagen cross-linkages, causing the fascia, ligaments, and tendons to be less distensible. Activity promotes connective tissue hypertrophy, whereas inactivity leads to atrophy. Physical activity also enhances the rate of collagen turnover, which shortens its life span. This turnover retards the effect of maturation of collagen cross-linkages and makes collagen more distensible (7).

### Cartilage

Cartilage requires mechanical loading and unloading to remain healthy. This helps maintain nutrition to the tissues. Cartilage rarely has a direct blood supply and derives most of its nutrition via diffusion. If deprived of bearing weight, the cartilage undergoes degeneration (8). With repetitive overuse, cartilage can break down over time and lead to symptoms such as pain.

### Ligaments

Ligaments are composed of approximately 70% collagen, along with ground substance and a larger percentage of elastin than tendons. They typically attach bone to bone and are important stabilizers of joints. Ligaments contain minimal blood supply, with most supplied by periarticular arterial plexuses. For example, the ACL, the main stabilizer of the knee against anterior translation of the tibia, has minimal intrasubstance arterial supply. The ACL does, however, receive some nutrition from the synovial fluid as well. The poor blood supply to ligaments explains the poor healing response in complete/partial injuries. The principles of collagen cross-linkages described in the tendon also apply to ligaments. Ligaments function to stabilize joints in concert with normal osseous alignment and musculo-tendinous stability. Ligaments also enhance proprioception via neurosensory receptors.

### Bone

Bone is a dynamic tissue that remodels in response to external stress. Bone remodeling/healing represents the spectrum of bone's response to stress (Wolff's Law). Bone is a hard tissue consisting of cells in a matrix of ground substance and collagen fibers. The fibers are impregnated with mineral substance, chiefly calcium phosphate and carbonate. In addition to failure of bone secondary to repetitive stress (i.e., stress fractures), bony malalignment will also predispose the athlete to injury. Examples of malalignment include valgus alignment of the knee predisposing to patellar maltracking or a cavus foot predisposing to Achilles tendinitis.

## BASIC PRINCIPLES OF NONOPERATIVE FUNCTIONAL REHABILITATION

Several basic principles can be applied to almost any acute sports injury, as outlined in Table 53-1. These rehabilitation phases provide a stepwise approach to treat and assess the progress of an athlete with an acute injury. Immobilization is avoided as much as possible because of its multiple detrimental effects on tissue healing (e.g., scar formation, contracture, and atrophy).

### Phase I: Decrease Pain and Control Inflammation

The initial phase of treatment is to control the inflammatory reaction that occurs after an acute injury and its associated

- V. Sports/task specific activities

Note: One should always remember to identify and address deficiencies along the entire kinetic chain.

pain, which inhibits muscle function. It should be noted that mediators involved in the inflammatory response are also important factors involved in the healing of soft-tissue injuries. Therefore, although the goal is to control the inflammatory response, eliminating it completely could be detrimental to tissue healing. The PRICE (protection, rest, ice, compression, elevation) approach is well known to those who care for athletes.

After an injury, the area can be protected either by splinting, bracing, or taping/wrapping. It is very rare that any ligamentous or musculoskeletal injuries would require casting, which is usually avoided. Crutch ambulation (usually weight bearing as tolerated) for lower extremity injuries can be very helpful until a normal, pain-free gait pattern can be reestablished. Bracing should be limited to that which protects the specific area while allowing for full motion at other areas. It is often possible to use the same brace to facilitate early protective motion as well as return to functional activities later in the rehabilitation process (e.g., a double upright hinged knee brace following a medial collateral knee sprain).

Rest should be prescribed carefully, as it is important that the athlete does not become deconditioned during the rehabilitation of an injury. Fatigue results in a decrease in neuromuscular functioning and joint control, thereby placing greater dependency on the static stabilizers of joints (i.e., the ligaments), placing them at greater jeopardy for injury. Therefore, the proper term is *relative rest*, which means that while the affected area is rested, the remainder of the body is exercised. In particular, cardiovascular conditioning must be maintained. This can be done by alternative exercises that allow for protection of the injured area while stressing the cardiovascular system at the same intensity, duration, and frequency as the athlete had previously trained. For example, a running athlete who suffers a lower extremity injury that must be unloaded can use deep-water vest running at the same intensity level as before the injury. This has allowed athletes to maintain their cardiovascular fitness level while their injuries heal, allowing for safe return to play at close to the preinjury level and possibly prevent additional injuries.

Ice controls the initial inflammatory response and facilitates pain control immediately following an injury. The affected areas should be generally iced 20 minutes four to five times a day, or more often if possible. Ice is used for its properties of vasoconstriction, which limits the edema as well the release of vasoactive and pain factors, such as bradykinins and leukotrienes. Ice also can decrease conduction along pain fibers and act as a counterirritant to assist in pain control and to reduce muscle spasm. There are various methods of icing that include ice pack, ice massage, ice immersion, and devices that combine both ice and compression.

Compression is also used in an effort to limit the edema in the injured area. Ace wrapping is often used but can be problematic because of the difficulties in getting uniform or gradient (from distal to proximal) compression. A compressive stockinette (e.g., Tubigrip) can be very helpful in this regard. A sleeve can be cut to whatever size is necessary and simply

applied. For additional compression, it can be folded over onto itself. Care must be taken to avoid excessive pressure over bony protuberances or superficial nerves. Compressive braces can also be effective (e.g., air splints for ankle sprains). Finally, devices that combine icing with compression have been found to be very useful and effective in the postinjury as well as postoperative rehabilitation of athletic injuries. They can be used not only by therapist and athletic trainers but also at home by motivated athletes.

Elevation is yet another means to control postinjury swelling. The injured limb should be elevated above the level of the heart to optimally assist with venous and lymphatic drainage and therefore control edema. Keeping the lower extremities out of a dependent position is helpful as well in limiting the pooling of inflammatory and posttraumatic products.

Additionally, nonsteroidal antiinflammatory drugs (NSAIDs) for a short period of time, if not contraindicated, and electrical stimulation can assist with both inflammation and pain control. Whether they offer clear advantages over using just the above program is a matter of debate, but if available and not contraindicated, appear reasonable.

## Phase II: Restore Normal/Symmetric Range of Motion

Pain and swelling can inhibit motion or produce altered motor patterns that, if established, often require retraining to restore proper motor control. An example is an athlete with an antalgic gait following a knee or ankle injury. This movement pattern must be discouraged while the area is gradually mobilized. Immobility will result in scar and contracture and therefore is not recommended. Range of motion (ROM) allows for controlled stress to a joint, which will stimulate proper collagen deposition. Motion provides sensory input to the central nervous system, which stimulates the proprioceptive system as well as modulates pain via the Gate theory. In the early phase, pain-free movement of a joint and stretching that prevents contractures are encouraged as the motion that results in stress on the injured area is avoided. As the pain and inflammation subside, more aggressive stretching and mobilization continue until symmetric (to the unaffected limb) motion is achieved with normal movement patterns.

## Phase III: Restore Normal/Symmetric Strength

Strengthening a painful, inflamed limb that lacks normal ROM can result in further problems that can delay recovery from injury. Therefore, a stepwise approach toward strengthening must be used. In the early postinjury phases, pain-free isometric contractions performed several times throughout the day are encouraged in an effort to retard muscular atrophy. A simple method is to recommend 10-second contractions, with 10 repetitions, 10 times a day. These isometric contractions may need to be performed through multiple angles as the strengthening is specific to the manner and position in which a muscle is trained. As the injured area recovers and ROM is restored, isotonic strengthening can begin if possible. Currently, there is no significant role for isokinetic strengthening because of poor functional

carryover. To that end, closed kinetic chain exercise should begin as soon as possible and progressed as able. Resistance training can be in the form of exercising against gravity, free weights machines, and resistance tubing. The strengthening should be as functional as possible, attempting to match the demands of the sport. Resistance tubing strengthening is attractive because of its ease and simplicity; however, the greatest tension with resistance occurs at the end ROM, where the muscle is usually weakest and the joint is most vulnerable. Therefore, this should be reserved for later stages of the strengthening program. In addition, the use of plyometric exercise should be included as the athlete is preparing to return to sport, because such training may ready the athlete for explosive bursts that are often a necessary part of many high demand sports.

#### Phase IV: Neuromuscular Control (Proprioceptive) Retraining

In order to dynamically control a joint during sport activity, there needs to be not only full ROM and normal strength but also adequate dynamic motor control. Specifically, the injured joint needs to be stabilized by synchronous activation of appropriate muscle groups so that the larger, more powerful muscles may safely produce the necessary force required in sports activity. Many injuries can result in proprioceptive loss that may predispose an athlete to repeat injury. As in other areas addressed in the rehabilitation process, the proprioceptive system needs to be progressively challenged in order for progress to be made. Simple proprioceptive training can include seated exercises with a wobble board for lower extremity injuries or loading exercises of the arm either on a table or wall. As the athlete recovers, and assuming that there is near full ROM and strength, the proprioceptive system is progressively challenged (e.g., balancing on a single leg while catching and throwing, balancing with eyes closed). Proprioceptive training requires a great deal of one-on-one work with a therapist or trainer and often creativity in developing ways to challenge the proprioceptive system that corresponds to the athlete's sport (9).

#### Phase V: Return to Sport Activities

As the athlete completes these phases, the therapist or trainer must then begin the transition to return to sport. This occurs as the athlete successfully meets the challenges of the previous phases. The athlete then is put through activities that replicate the demands of the sport. For example, a basketball player will be given various drills that include running, cutting, and jumping (and landing) using optimal biomechanics. Once the athlete demonstrates that he or she can successfully negotiate the various drills and challenges that will occur in the sport in a controlled situation, then it should be clear to everyone on the team (including the athlete) that he or she can safely return to their sport.

### CARDIOVASCULAR ISSUES IN SPORTS

An integral part of the preparticipation physical examination for athletes is the cardiovascular evaluation. The goal of this

evaluation is to identify athletes who are at risk for sudden cardiac death during vigorous physical activity. By applying elements of the personal history, the family history, and the physical exam, the most important signs and symptoms of the most common cardiac reasons for sudden death can be obtained. These include hypertrophic cardiomyopathy (HCM), selected arrhythmias, coronary artery anomalies, ruptured aortic aneurysms, and commotion cordis (1). In particular, HCM has received much attention in the press and in the literature as it has taken the lives of several high profile athletes. It is the primary cause of sudden atraumatic death in athletes, responsible for nearly 35% of those deaths (10). We will briefly discuss HCM below because it is important to understand the pathophysiology in order to be able to recognize the signs and symptoms of this silent killer.

#### Hypertrophic Cardiomyopathy

HCM is a hereditary condition that occurs as commonly as 1:500 in the adult population (11). It is most commonly transmitted via an autosomal dominant pattern in which there is a genetic defect in the sarcomere contractile proteins (12). This leads to an increased ventricular muscle mass that is characteristically the hallmark of this condition. It is important to note that there is *not* an associated increase in actual ventricular cavity size; just a hypertrophy of the muscle tissue itself. This is important because it can often be difficult to differentiate HCM from a conditioned athlete's heart. A well-conditioned athlete can sometimes develop a structural remodeling and an increased ventricular cavity to accommodate the larger ejection fraction that develops due to their increased efficiency for oxygen extraction at the tissue levels, while at the same time maintaining normal systolic and diastolic function (11). In contrast, in HCM, there is a severe *net reduction* in actual inner ventricular cavity size because of the much enlarged and hypertrophied muscle mass.

In HCM, there is also evidence of reduced compliance secondary to the inability to adequately relax the hypertrophied muscle mass. This causes diastolic dysfunction, which in turn leads to an increased left ventricular end-diastolic pressure (LVEDP) and subsequent impedance to appropriate diastolic filling. This increase in LVEDP may then lead to the development of a pressure gradient between the left ventricle and the aorta. This gradient is clinically significant to the sports medicine physician because it can be affected with certain maneuvers aimed at increasing or decreasing left ventricular end-diastolic filling. Techniques such as Valsalva maneuver or changing positions from standing to squatting and back to standing are aimed at increasing or decreasing left ventricular end-diastolic filling. If a murmur is present, these techniques will affect the quality of the murmur differently depending on its etiology.

A systolic murmur can occasionally be heard in HCM. It is the result of the pressure gradient between the left ventricle and the aorta that was previously mentioned. Any maneuver that *decreases* left ventricular end-diastolic filling, such as Valsalva or rising from squatting to standing, will subsequently

lead to dynamic obstruction in the left ventricular outflow tract, thereby increasing the intensity of the HCM murmur. Conversely, the murmur is also ominous if it decreases in intensity when maneuvers to *increase* left ventricular end-diastolic filling are performed. Such maneuvers will alleviate dynamic obstruction in the left ventricle outflow tract, thus decreasing the murmur. Therefore, when a patient goes from standing to squatting and the murmur that the physician is hearing is decreased in intensity, this is a sign of abnormal hemodynamics and can cause the physician to be suspicious for HCM. Benign murmurs, on the other hand, will increase with squatting because blood return to the heart is increased; and they will decrease in intensity upon rising from squatting, as blood return to the heart diminishes (10).

The most common signs/symptoms of HCM are syncope or sudden cardiac death with exertion. Therefore, risk factors for HCM, as well as for all the other cardiovascular anomalies such as arrhythmias or ruptured aneurysms or coronary artery anomalies, must be understood and thoroughly investigated in the preparticipation physical exam evaluation.

### General Cardiac Evaluations

The guideline recommendations for preparticipation athletic screening of the cardiovascular system include a thorough evaluation of the family history, the personal and present medical history, and the physical evaluation (13,14).

Importantly, one should ask if there is a history of premature or sudden cardiac death, or if there have been any deaths of unknown etiologies in young family members. As mentioned earlier, HCM is a familial disease, as is Marfan's Syndrome, which can lead to ruptured aortic aneurysms. Thus, any history of prior sudden cardiac death, particularly in young family members, is imperative. It is also important to screen for history of heart disease in anyone in the family under the age of 50.

There are also elements of the personal history that are crucial to the cardiovascular evaluation of any athlete. Questions regarding medical history of heart murmurs can signify more than just a benign flow murmur. Likewise, systemic hypertension, particularly if it is not well controlled, can cause abnormal hemodynamics and add undue stress to the heart. The physician must also importantly inquire about exertional symptoms. Has the patient ever had exertional syncope or near syncope? Is there a history of exertional chest pain? Is there a history of dyspnea upon exertion that is out of proportion to the amount of exercise being performed? Have there been palpitations or irregular heartbeats? All of these could be symptoms of a heart that is struggling to meet the demands of the exercising musculoskeletal system (14,15).

The physical exam, as we have alluded to, is key to identifying possible at-risk athletes. Auscultation of a murmur warrants further evaluation and requires employment of the previously described tactics (Valsalva, squatting, standing) to be able to demonstrate the qualities of the murmur and to possibly define some pathology. Of course, any heart rhythm abnormality needs to be evaluated further. Pulses must be

palpated for intensity and heart rhythm. Lateral and inferior migration of the point of maximal impact (PMI) of the heart on the chest wall may also be a sign of left ventricular hypertrophy. If any of the above-mentioned scenarios are uncovered, the athlete must be precluded from exercise until further workup has occurred with EKG, echocardiogram, and possibly a Holter monitor.

Interestingly, Corrado et al. performed a multiyear study in Italy, analyzing the efficacy of a nationally implemented standardized preparticipation cardiovascular evaluation for the detection of at-risk athletes for sudden death. Their study also included an EKG on top of all the previously described history and physical exam (16). This multiyear study concluded that there was decreased incidence of sudden cardiac deaths since the initiation of the national screening program secondary to better detection of the at-risk athletes and precluding them from participation. It prompted some here in the United States to ask questions about whether we need to have a national standardized preparticipation screening program, and if we do, should we add the EKG to the preparticipation evaluation as a routine screening test to complement the history and physical exam. However, there have been questions raised regarding true cost effectiveness and utility of the EKG as a part of the routine screening cardiac evaluation (17).

Needless to say, an aggressive and focused preparticipation evaluation must be an essential part of the armamentarium of the sports medicine physician. He or she must understand the pathophysiology of the most common causes of sudden cardiac deaths in athletes, as well as be able to identify which athletes are at risk for this based on their preparticipation evaluation. The physician must also serve as an educator to coaches, players, and parents about the warning signs of dangerous cardiac scenarios (1).

### CONCUSSION IN SPORTS

A concussion results from trauma transmitted either directly or indirectly to the head, causing impairment of the brain's normal function (Table 53-2). This impairment may last from seconds to days. At times, dysfunction or postconcussive symptoms (headache, dizziness, tinnitus, irritability, memory impairment, nausea/vomiting, fatigue, etc.) can last months to years. Concussion is a type of brain injury, which can be classified as minor, mild, moderate, or severe (18).

Documented signs and symptoms of a brain injury (concussion) include amnesia (retrograde/antegrade), loss of consciousness (LOC), headache, dizziness, nausea, attentional deficit, and blurred vision. Additional features have been mentioned and include confusion/disorientation, being "dazed" or having one's "bell rung," inability to relate game specifics (period, opponent, score, plays), dizziness, seeing flashing lights, tinnitus, diplopia, impaired concentration, slurred speech, inappropriate behavior (laughing/crying), irritability, altered taste or smell, impact seizure, imbalance, and decreased ability to play the sport (19).

**TABLE 53.2 Concussion**

Concussion is defined as a complex pathophysiological process affecting the brain, induced by traumatic biomechanical forces. Several common features that incorporate clinical, pathological, and biomechanical injury constructs that may be used in defining the nature of a concussive head injury include

1. Concussion may be caused by a direct blow to the head, face, neck, or elsewhere on the body, with an “impulsive” force transmitted to the head.
2. Concussion typically results in the rapid onset of short-lived impairment of neurological function that resolves spontaneously.
3. Concussion may result in neuropathological changes but the acute clinical symptoms largely reflect a functional disturbance rather than structural injury.
4. Concussion results in a graded set of clinical syndromes that may or may not involve LOC. Resolution of the clinical and cognitive symptoms typically follows a sequential course.
5. Concussion is typically associated with grossly normal structural neuroimaging studies.

Source: Aubry M, Cantu R, Dvorak J, et al. Summary and agreement statement of the first international conference on concussion in sport, Vienna 2001. Recommendations for the improvement of safety and health of athletes who may suffer concussive injuries. *Br J Sports Med.* 2002;36(1):6–10; Aubry M, Cantu R, Dvorak J, et al. Summary and agreement statement of the first international conference on concussion in sport, Vienna 2001. *Phys Sport Med.* 2002;30(2):57–63.

The evaluation of the athlete suspected of a concussion should include a history of past head and neck injuries (including orofacial), severity of impact (magnitude of force, linear, rotational), prior structural deficits if the athlete had a prior injury, and genetic phenotype if known (apolipoprotein). This should be combined with the detailed evaluation of the current episode. Although LOC is an appropriate concern, it appears insensitive for most concussions, and amnesia may be a better measure of severity.

If a history of multiple concussions is obtained, care should be taken to quantify severity of the precipitating events and duration of concussive symptoms. It appears that a history of concussion results predisposes to subsequent brain injuries.

Postconcussive symptoms include headaches, nausea, vomiting, drowsiness, numbness or tingling, balance impairment, vertigo, sleep impairment, light or noise sensitivities, difficulty concentrating or remembering, sadness, anxiety, dizziness, irritability, or fatigue. Although postconcussive symptoms are controversial, they are felt to arise from either the direct brain impairment or a psychological reaction to the brain injury itself.

Concern for concussion should go beyond the immediate injury. If an athlete were to return to competition without being fully recovered, he or she could sustain a second injury of greater severity. Schneider first described such a syndrome in 1973 (20). It was later coined “second-impact syndrome” by Saunders and Harbaugh in 1984 (21). Second-impact

syndrome results from a person sustaining a second brain injury before symptoms of a prior concussion have cleared. This second trauma can be relatively minor in severity and may not involve the head. It is believed that the brain’s vascular autoregulation becomes impaired from the first injury, leading to engorgement within the cranium. Increased intracranial pressure ensues, resulting in herniation of the medial temporal lobes through the tentorium or cerebellar tonsils through the foramen magnum. Clinically, the athlete suffers a second head injury and becomes dazed. Within 15 seconds to a couple of minutes, the athlete rapidly decompensates. He or she collapses, becomes semicomatose, and suffers from pupil dilation, loss of eye movements, and respiratory failure.

The precise incidence of second-impact syndrome is unknown, but from 1980 to 1993, only 35 presumed cases were reported to the National Center for Catastrophic Sports Injury Research in Chapel Hill, North Carolina. Seventeen of these cases were confirmed. The mortality rate is 50%, and the morbidity rate is 100% (22).

Impact seizures are an uncommon result of a mild head injury. They develop within seconds of the insult and are not associated with any structural brain injury or long-term risks. The seizures do not need treatment, and the athlete should not necessarily be eliminated from sport.

Concussions are more common in some sports, including American and Australian football, ice hockey, rugby, and soccer. The National Center for Catastrophic Sports Injury Research’s database compiles statistics on baseball, ice hockey, tennis, basketball, lacrosse, track, cross-country skiing, volleyball, field hockey, soccer, water polo, football, softball, wrestling, gymnastics, and swimming. Estimated annual incidence of concussions is approximately 300,000 in the United States. Concussion rates per 1,000 player hours range from 0.25 to 23.0 (23).

Many different scales have been developed to evaluate concussed athletes for research purposes (Cantu, Colorado, American Academy of Neurology, Virginia Neurological Institute, Torg, etc.). Each includes parameters of consciousness and amnesia with varying importance to determine the grade or severity of injury. Currently, posttraumatic amnesia or working memory is felt to be of greater importance than LOC. People have tried abbreviated sidelines psychological batteries (24), balance (25) and cerebellar physical examination maneuvers, and assistance from coaches and athletic trainers for return-to-play evaluation. Recent research with more sensitive instruments demonstrates impairment in conceptual thinking (26), sustained attention and visuo-perceptual processing (27), and reaction time (28,29). Currently, clinicians have no scientifically validated information on clinical management of concussions or treatment effects on long-term outcomes, though studies are currently on-going.

Minor traumatic brain injury (TBI) has not been discussed in the literature as such. An athlete sustains a momentary loss or alteration in consciousness and has memory impairments that may be unrecognized. Often athletes are evaluated (usually football players), who show signs and symptoms of

a mild TBI when there has been no clear identifiable event. It is unclear whether their symptoms are the result of many “mini” concussions, one blow to the head they cannot recall, or repetitive acceleration-deceleration trauma to the head. These seemingly less severe concussions, in which no LOC occurs, may have greater long-term neurologic sequelae than a grade 2 concussion, in which a significant period of LOC exists. Further contributing to the difficulty in grading concussions is the underreporting of grade 1 concussions by the athlete. This occurs because of his or her fear of being withdrawn from the contest or because the athlete feels it is “part of the game.” Athletes commonly refer these milder concussions as getting the “bell rung.” One must question whether they are truly milder head injuries. This should be taken into consideration when evaluating an athlete. Studies are currently ongoing on this subject matter.

Mild head injury generally has no LOC, posttraumatic amnesia of less than 1 hour, and a Glasgow Coma Scale of 15 (30). The greatest number of concussions falls into this category of severity (including the “minor” TBI) (31). Because the Glasgow Coma Scale is not sensitive enough to be useful in the evaluation of a mild TBI, and LOC also appears to be too insensitive, more weight has been placed on amnesia.

Moderate TBIs generally have no LOC of less than 5 minutes, and posttraumatic amnesia from 1 to 24 hours, whereas severe TBIs have an LOC greater than 5 minutes and posttraumatic amnesia greater than 24 hours.

Paper-and-pencil testing (McGill ACE, SAC) and computerized evaluations (IMPACT, CogSport, etc.) are currently being researched (National Football League, National Hockey League, Australian football, Pennsylvania State University, University of Pittsburgh, etc.) in an attempt to develop a quick, simple, cost-effective, and accurate adjunct to the clinical evaluation for evidence-based decision making and return-to-play guidelines. Many of these are being implemented in the preseason as baseline tests in many high schools and universities around the country, with the goal being to retest an athlete after a concussion occurs. The athlete’s progress can be tracked based on his or her scores in these evaluations. This serves, as stated above, as an adjunct to the clinical evaluation for decision making regarding a return-to-play timeframe.

There had been no consensus regarding concussions or return to play until a conference was held in 2001 in Vienna (18) (Table 53-3). The consensus is that when an athlete is initially diagnosed with a concussion, he or she should not return to the current practice or game. He or she should have continued, intermittent monitoring for deterioration. There should be a medical evaluation if concern for a concussion was made by someone other than a physician. Return to play should be in a stepwise fashion, and if doubt is present, the athlete should be held from competition.

Return to play should include no postconcussive symptoms at rest or exertion, consideration of the concussion scales, and prior history of the athlete and his or her injuries. Some institutions have preparticipation neuropsychological

**TABLE 53.3 Concussion Guidelines from the 2001 Vienna Concussion in Sports Guidelines (CISG)**

- Revised definition
- Strength and weakness of existing concussion guidelines (no singly system endorsed)
- Absence of scientifically validated return-to-play guidelines
- Defined signs and symptoms of acute concussion
- Cognitive (confusion, amnesia, LOC, disorientation)
- Symptoms (headache, dizziness, nausea, loss of balance, “dinged” or stunned, seeing stars or flashing lights, tinnitus or double vision, sleepiness, sleep disturbance, fatigue, slowness, etc.)
- Signs (LOC/impaired consciousness, impaired coordination, impact seizure, gait abnormality, slow to answer or follow direction, distracted-poor concentration, inappropriate behavior, vomiting, vacant stare, slurred speech, personality change, poor game/practice play, etc.)
- Neuropsychological testing is a cornerstone tool
- Neuroimaging not essential for uncomplicated concussion
- Research is ongoing and vital
- Rehabilitation program essential
- Return-to-play protocol (no activity until asymptomatic → light aerobic activity → sport-specific training → noncontact drills → full contact practice → game play → able to progress as long as asymptomatic)
- Prevention—rule changes and enforcement of rules are vital
- Education—promotion of fair and ethical play in sports

Adapted from Aubry M, Cantu R, Dvorak J, et al. Summary and agreement statement of the first international conference on concussion in sport, Vienna 2001. *Phys Sport Med*. 2002;30(2):57–63.

batteries on athletes, which can be repeated and compared with themselves, as well as age-matched and position-matched controls. This can be a great assistance in the decision-making process.

## CERVICAL SPINE INJURIES IN SPORTS

Cervical spine–related injuries are relatively common in contact/collision sports, such as football and wrestling. These injuries can include trauma to the tissues of the neck, including the muscles, ligaments, discs, and bones, as well as the neurologic structures, such as the nerve roots and spinal cord.

### Cervical Disc

As with the general population, cervical disc disease is seen in the more mature athlete. Some sports such as football and wrestling appear to increase the risk of developing a cervical disc syndrome. Cervical disc disease most commonly affects C5 to C6, followed by C6 to C7 and then C4 to C5. This pattern roughly corresponds to the amount of normal motion that occurs at each level, with areas of greater motion (i.e., C5

to C6) developing degeneration sooner. Some physicians have divided cervical disc disease into soft and hard disc diseases. The soft disc refers to an acute disc herniation, usually in a younger person with or without neurologic involvement, depending on the degree of mechanical or chemical irritation by the nucleus pulposus on the nerve root structures. The hard disc is the result of events occurring over time and the progressive decline in the cervical disc and surrounding structures resulting in spondylosis. This degeneration process is characterized by disc bulges, herniations, thickening of the posterior longitudinal ligament, thickening of ligamentum flavum, degeneration of the synovial facet joints, or osteophytes. These anatomic changes result in a greater likelihood of structural compromise or impaired spinal kinematics. These changes may result from the athletes' sport or, as with the general population, chronic impaired loading through altered posture and inappropriate loading of the various spinal structures over time. Of specific note, radiographic changes correlate poorly with signs and symptoms that patients exhibit (Figs. 53-1 to 53-3) (32,33).

### Cervical Cord Neuropraxia

Cervical cord neuropraxia results from an injury to the spinal cord presenting with complete transient paralysis, motor impairment, sensory changes, or a combination of these in at least two limbs. Transient quadriplegia is a rare cervical spine injury caused by axial loading of the neck in extension or flexion that results in nonpermanent complete sensory and motor impairment in all four limbs resolving in 10 minutes to 48 hours (34). One should remember that any neurologic impairment in more than one extremity is a central nervous system injury unless proven otherwise (sometimes referred to as burning hands syndrome).

Obersteiner originally described this as a spinal cord concussion in 1879 (35). It has been estimated at 1.3 episodes per 10,000 athletes or an incidence of 6 h 10,000 athletes (36).

It appears that this is a neuropraxic injury from local cord anoxia and increased intracellular calcium (37). During hyperextension, a “pincer” effect can occur, causing the posterior inferior aspect of the superior vertebra and anterior superior aspect of the inferior vertebra to produce a resultant compression of the spinal cord. In this position, the diameter can narrow up to 30% (38). With associated spinal degeneration, even greater compromise can occur.

In the event of either a significant head injury in which a concomitant neck injury may be present or isolated cervical injury, the medical team should be appropriately prepared by having the correct equipment available and having practiced the evaluation and treatment of the athlete with this type of injury. This includes the possibility of spine-boarding the athlete and removal of the athlete's protective gear (i.e., facemask removal). An athlete who is wearing protective headgear (e.g., a helmet) with a suspected spinal injury should not have the helmet removed. It is imperative that the sideline physician understands how to protect the spine and coordinate spine-boarding and transportation of an athlete with a suspected spine injury.

In the evaluation of an athlete with suspected cervical disc disease, the location, referral pattern, quality of the symptom, and associated neurologic symptoms—such as Lhermitte's sign, balance/gait abnormalities, limb weakness, or bowel/dysfunction—must be obtained. This should occur to determine if additional structures have been damaged. A complete physical examination (including cervical tenderness and ROM), a detailed neurologic examination of the

**FIGURE 53-1.** Good cervical posture—lateral view. The head is aligned over the cervical spine with maintained lordosis and normal structural loading.

**FIGURE 53-2.** Poor cervical posture—lateral view. The head is protracted forward with extension of the occiput and loss of lordosis.

**FIGURE 53-3.** Cervical spine radiograph showing osteoarthritic changes—lateral view. Cervical osteoarthritis from chronic abnormal loading of the spinal elements (i.e., discs, facets, etc.).

upper and lower limbs (including power, sensation, reflex assessment, and a Spurling's maneuver), and evaluation for upper motor neuron signs (Hoffman, plantar responses, tone, etc.) are all necessary.

X-rays may be helpful in evaluating the athlete for a fracture, spinal instability (with the use of flexion/extension views), osseous degeneration, or destructive lesions from tumor or infection. Anteroposterior, lateral, open-mouth, and oblique views should be the initial evaluation. If pain or neurologic signs persist or ROM has not returned, further imaging should be considered. Magnetic resonance imaging (MRI) is probably the study of choice if not contraindicated. A fat-suppressed image should be included to evaluate for ligamentous injury, especially when instability is seen on radiographs or clinically suspected. The spinal diameter and relative space can be evaluated. Normal midsagittal diameter on plain x-rays should be 14 to 23 mm. If the canal is less than 13 mm, it is considered stenosis (39).

Torg et al. introduced a ratio to assist with measuring and stratifying persons at risk for cervical cord neuropraxia from spinal stenosis (40). A lateral cervical spine x-ray is obtained and measurements are made. The Torg ratio is the distance from the midpoint of the posterior aspect of the vertebral body to the nearest point on the corresponding spinolaminar line divided by the anterior to posterior width of the vertebral body. It is of limited utility in screening athletes for participation due to its low specificity and positive predictive value despite its high sensitivity.

**TABLE 53.4** Cervical Spine Table

1. Canal/vertebral body ratio  $\leq 0.8$  in asymptomatic individuals, no contraindication.
2. Ratio of  $\leq 0.8$  with one episode of cervical cord neuropraxia, relative contraindication.
3. Documented episodes of cervical cord neuropraxia associated with intervertebral disc disease and/or degenerative changes, relative contraindication.
4. Documented episode of cervical cord neuropraxia associated with MRI evidence of cord defect or cord edema, relative/absolute contraindication.
5. Documented episode of cervical cord neuropraxia associated with ligamentous instability, symptoms of neurological findings lasting more than 36 h and/or multiple episodes, absolute contraindication.
6. Spear tackler's spine, absolute contraindication.

From Torg JS, Ramsey-Emrhein JA. Management guidelines for participation in collision activities with congenital, developmental, or postinjury lesions involving the cervical spine. *Clin J Sport Med.* 1997;7(4):273–291, with permission.

### Return to Play

Return-to-play considerations should initially include normal ROM or thorough imaging evaluation—if ROM is abnormal—and a normal neurologic examination (41,42). There are absolute and relative contraindications to returning an injured athlete to play (Table 53-4).

With traumatic lesions, some athletes may return to sport without limitations, depending on the injury, healing, and treatment. Atlantoaxial instability noted on lateral flexion-extension views, rotatory fixation from computerized tomography (CT), fused C1 to C2 segments, and acute spine fractures are an absolute contraindication for return to play. Healed nondisplaced Jefferson's fractures, odontoid fractures (type I and II), and healed lateral mass C2 fractures with pain-free full ROM and no abnormal neurologic signs are relative contraindications.

If lateral flexion-extension x-rays demonstrate greater than 3.5 mm of horizontal translation from one vertebral body to the adjacent in the middle and lower cervical spine, or greater than 11 degrees of angulation of adjacent vertebral bodies, return to play is absolutely contraindicated (42,43). Healed fractures of a stable displaced vertebral body compression fracture without an anteroposterior sagittal component or a stable fracture involving the posterior neural ring in individuals who have a normal examination have a relative contraindication. If the examination is abnormal, or if there is superimposed ligamentous laxity, then the contraindication is absolute.

Acute intervertebral disc injuries are an absolute contraindication, but when they have resolved and the patient has a normal exam, the athlete may return to play. Abnormal neurologic signs, loss of motion, an acute "soft" herniation superimposed onto "hard" preexisting abnormalities with/without congenital stenosis, and loss of the normal cervical lordosis are all absolute contraindications.

A one-level fusion with normal alignment, motion, and examination incurs no restriction. A two- to three-level fusion and normal examination represent a relative contraindication, whereas a fusion extending more than three levels represents an absolute contraindication to play (42).

### Proximal Nerve Pathology

The most common cervical root and brachial plexus injury in an athlete is a “burner or stinger.” An athlete (most commonly a football player) sustains a trauma resulting in symptoms of pain and paresthesias down one limb (44). Symptoms usually last less than 1 minute and typically there are no abnormal neurologic signs on examination. Two common mechanisms of trauma have been described. First, the cervical spine may be side bent and extended, causing compression on an exiting nerve in the intervertebral foramen. Alternatively, the shoulder may be forcefully depressed while the head is driven in the opposite direction, causing traction on the nerve. A direct blow to the plexus can also result in dysfunction, but less commonly (45). The injury usually affects the upper cervical nerves of the plexus (C5 to C6), but can extend to involve additional portions of the plexus. The strength, sensation, and reflexes of the upper limbs should be evaluated on physical examination.

Electrodiagnostic studies can be helpful in localizing the site of neurologic injury (cervical roots vs. brachial plexus vs. peripheral nerve) and can be useful in objectifying the severity. They are not as helpful in determining whether an athlete is ready to return to participate because of the delay between nerve recovery and the normalization of electromyographic (EMG) findings. Once diagnosed, radiographs are usually indicated if symptoms are persistent or recurrent. They will most often be normal, but may show evidence of degenerative disc disease or intervertebral foraminal narrowing. A physical therapy program should be designed that addresses tackling technique, neck ROM, postural alignment, muscle shortening from spasm, strengthening of the involved muscles, and muscle retraining/proprioception so the neck and shoulder stabilizers “functionally” protect the neck and nerves from further potential injury. Adequate fitting of shoulder pads and lifters should be employed, and the use of a neck orthosis such as the “Cowboy Collar” should be considered. Neck orthoses are theorized to prevent excessive cervical extension, thereby decreasing the potential traction or compression that may result from contact. Recurrent burners can be a serious problem. For those athletes who have recurrences or are left with neurologic deficits, an MRI may be needed. Since the long-term history of burners has not been studied, it is not known whether they have more long-lasting consequences.

It is very important to remember that “bilateral stingers” are extremely rare. If an athlete reports upper-limb symptoms in both arms, a spinal cord injury must be ruled out first and foremost.

## SHOULDER

The rotator cuff includes the supraspinatus, infraspinatus, teres minor, and subscapularis (SITS) muscles. Its function is to maintain the humeral head centered on the glenoid (45a) during arm motion. The “shoulder” is made up of three true joints and one pseudojoint. These include the sternoclavicular joint, acromioclavicular joint, glenohumeral joint, and scapulothoracic pseudoarticulation. The glenoid and acromion are portions of the scapula. Dynamic muscular control of the scapula is vital to the function of the shoulder as a cohesive unit (46).

On physical examination, active and passive ROM should be evaluated, including isolated testing of the glenohumeral joint and scapulothoracic rhythm. Strength, sensation, and reflexes in the upper limb should be evaluated to completely evaluate the shoulder as well as rule out concomitant neurologic injury. Specialized testing for impingement, instability, and labral and rotator cuff pathology should be performed as indicated.

### Rotator Cuff Injury

Rotator cuff tendinitis typically occurs either from scapular dysfunction causing subsequent impingement or rotator cuff dysfunction, allowing excessive movement of the humeral head and resultant impingement. Classically, Neer classified impingement into three stages (47). Stage 1 consisted of edema and hemorrhage of the tendon; stage 2, the development of fibrosis and tendinitis, usually occurring in patients older than age 25; and stage 3, the degeneration, bony changes, and tendon rupture, usually occurring after age 40. Jobe and Pink added a fourth stage, defining it as rotator cuff tears greater than 1 cm (48). With chronic, impaired motion, degeneration or tearing of the tendons can result. Weakness of the scapula stabilizers, especially when there is an underlying nerve injury (i.e., long thoracic neuropathy), can lead to inadequate scapula rotation during shoulder elevation. Muscle incoordination of the same muscles can similarly lead to inadequate scapula rotation and further narrow the outlet through which the supraspinatus tendon passes. Additionally, excessive scapula motion can cause repetitive irritation of the undersurface of the acromion, leading to remodeling as demonstrated as spurs or acromial “hooking.” This bony degeneration can cause narrowing and repeated impingement with damage to the rotator cuff. It is easy to appreciate that weakened, deconditioned, and dysfunctional muscles can precipitate a viscous cycle (Fig. 53-4).

The supraspinatus tendon has a vulnerable area (watershed) where its vascular supply can be compromised by tendon lengthening, thus causing ischemia. Isolated bicipital tendonitis as the primary cause of shoulder pain is uncommon and exists along the continuum of rotator cuff tendinitis secondary to its related proximity. Impingement is a result of

**FIGURE 53-4.** The examiner is performing Neer's maneuver: The arm is forward flexed passively and maintained in neutral rotation. A positive test occurs when the patient develops pain as the arm approaches full elevation.

biomechanical dysfunction of the shoulder and itself is not a pathologic diagnosis. This impingement causes pathology by repetitive compromise of the soft tissues of the shoulder girdle (Fig. 53-5).

### Shoulder Dislocation/Instability

Thomas and Matsen classified shoulder instability into two groups (49): TUBS, which stands for traumatic, unidirectional, Bankart, surgery, and AMBRI, which stands for atraumatic, multidirectional, bilateral, rehabilitation, and inferior capsular shift. These entities are not mutually exclusive, but give a construct with which to think about shoulder pathology.

Dislocation treatment depends on the patient's age, activity level, and the number of subluxations and dislocations experienced. Epidemiological studies of shoulder dislocations have shown an approximate 90% redislocation rate in those younger than age 20, moderate risk from age 20 to 40, and an approximate 10% rate for those older than age 40 (50). There appears to be no consensus of the period of immobilization after a dislocation and the resultant recurrence rate. Periods from a few days to 6 weeks, with and without a rehabilitation program, have been attempted. The redislocation risk may depend, in part, on the patient's age, amount of trauma sustained, postdislocation activity level, and postdislocation rehabilitation program.

**FIGURE 53-5.** The examiner is performing Hawkins's maneuver: The arm is abducted to 90 degrees and placed in the scapular plane while passive internal rotation is performed. A positive test causes pain as the greater tuberosity entraps the supraspinatus tendon under the coracoacromial arch.

For the shoulder to maximally perform its function, it sacrifices bony stability for mobility. This highly mobile joint uses dynamic muscular control as its greatest stabilizer. Additional factors that contribute to stability are glenoid concavity, whose surface is increased by the labrum; negative intraarticular pressure; capsule and ligaments; and compression from the rotator cuff muscles. The static stabilizers include the anterior band of the inferior ligament complex for anterior translation, posterior band of the inferior glenohumeral ligament complex for posterior motion, and the superior glenohumeral ligament for inferior movement (51). The dynamic stabilizers include the rotator cuff muscles. These stabilizers contribute to varying degrees, depending on arm position.

On physical examination, one can use the apprehension and relocation test, sulcus sign, load and shift test (drawer), or "jerk" test. It is important to assess for generalized ligamentous laxity and the strength of the scapular and rotator cuff muscles, as well as ruling out neurologic causes for weakness and instability. In addition, many patients will also have posterior capsular tightness, which needs to be assessed and addressed in the rehabilitation of the athlete.

### Rehabilitation of the Shoulder

Initially, pain control and inflammation reduction are required to allow progression of healing and the initiation of an active

rehabilitation program. This can be accomplished with a combination of relative rest, icing (20 minutes three to four times a day), electrical stimulation, and acetaminophen or an NSAID. This is the initiation of the therapy program. The following progression can be added as the patient tolerates. If these are not sufficient, more aggressive intervention, such as corticosteroid injections, can be considered. Passive modalities in isolation have never been proven to be of benefit.

After the pain has been managed, restoration of motion can be initiated. Specifically, internal rotation should be addressed because it is lacking in most patients. Poor internal ROM results from a tight posterior capsule or dysfunction of the rotator cuff, causing the humeral head to translate forward. With repetitive motions, this can cause a great deal of shearing on the anterior labrum and eventually result in either degeneration of the labrum or tearing.

The third phase of treatment is strengthening and should be performed in a pain-free range. The scapulothoracic stabilizers should first be addressed because the glenoid is the platform on which the arm moves. Strengthening can then progress to the rotator cuff muscles and then to the shoulder's prime movers.

The fourth phase is proprioceptive training. This is important in order to retrain neurologic control of the strengthened muscles. It provides improved dynamic interaction and coupled execution of tasks for harmonious movement of the shoulder and arm.

The last phase of rehabilitation is to return to task- or sport-specific activities. This is an advanced form of proprioceptive training for the muscles to relearn prior activities. This is important and should be overseen to be sure that the task is performed correctly and to eliminate the possibility of reinjury or injury in another part of the kinetic chain from improper technique. The rehabilitation begins at a cognitive level, but must be practiced until it transitions to unconscious motor programming (52).

As with all musculoskeletal rehabilitation, the entire body must be taken into consideration. Abnormalities in the kinetic chain can also affect the shoulder. If there are restrictions or limitations in ROM or strength, the forces will be transmitted to other portions of the kinetic chain, resulting in an overload of those tissues and possible injury.

### Nerve Injuries About the Shoulder

Several peripheral nerve injuries in the region of the shoulder are seen in the athletic population. Neuropathies of the axillary, suprascapular, and long thoracic nerves can be the result of the idiopathic condition Parsonage-Turner syndrome. All three can also be the result of trauma. The axillary nerve, which innervates the deltoid and teres minor, is the most commonly injured with anterior shoulder dislocations (53). The suprascapular nerve, which innervates the supraspinatus and then infraspinatus, is rarely associated with glenohumeral dislocations, but can be injured from repetitive trauma that is probably the result of traction. Entrapment can also occur at the suprascapular notch, leading to involvement of both the

supraspinatus and infraspinatus, or at the spinoglenoid notch, leading to involvement of only the infraspinatus. Compression can occur at either notch as the result of a ganglion cyst or a hypertrophied ligament. The largest case series of suprascapular neuropathies at the level of the spinoglenoid notch has been reported in volleyball players. Other sports with a high incidence of suprascapular neuropathies include tennis, baseball, and weight lifting. Long thoracic neuropathies have been reported in large numbers, but as individual case reports. The problem is that a good biomechanical etiology has not been well established. These nerve injuries not only lead to weakness of the serratus anterior and winging of the scapula, but also lead to inadequate scapula rotation during shoulder abduction. This commonly results in supraspinatus impingement syndrome.

### Brachial Plexopathies

Brachial plexus injuries in sports are uncommon but can be devastating, with potentially lifelong consequences. They most commonly occur as the result of a "burner or stinger." Classifying these injuries can be somewhat confusing, depending on how one defines the brachial plexus. The anatomist defines the plexus as beginning at the point where the cervical spinal nerves have joined to form the upper, middle, and lower trunks. Injuries proximal to the trunks would be considered cervical root or spinal nerve injuries. Clinicians more commonly define the cervical roots as part of the plexus. Based on the relationship of the dorsal root ganglion to the site of injury, they further define injury to the plexus as preganglionic or postganglionic. Because it is our contention that most burners are cervical root injuries, one can label these as preganglionic plexus as well. This type of classification would greatly increase the incidence of plexus injuries.

Probably the second most common cause of brachial plexus injuries are shoulder dislocations. These are usually anterior glenohumeral dislocations and can injure either a cord (usually the posterior cord) or an isolated nerve (usually the axillary nerve). These patients often have their shoulders immobilized for at least a brief period of time so that more subtle neurologic deficits may not be immediately recognized. Electrodiagnostic studies are often necessary to objectify weakness and rule out a nerve injury.

Parsonage-Turner syndrome is an idiopathic cause of brachial plexitis. Strictly speaking, this is not a sports injury, but because of its idiopathic nature, the athlete often tries to attribute an athletic event or activity as the cause of the nerve dysfunction. The classic presentation of acute onset of pain lasting 1 to 2 weeks with no clear trauma should make one suspect this diagnosis. Weakness is delayed in its onset, and the pain usually will abate spontaneously. Symptoms will often follow a viral illness, and at the time of exam, most provocative maneuvers are negative. There is no current treatment, although antiviral drugs may prove to play a role in the future. Management usually is the palliative treatment of the pain followed by appropriate physical therapy when residual neurologic deficits exist. The most commonly involved nerves are the upper trunk

of the brachial plexus, suprascapular, axillary, and long thoracic nerves. Long-term prognosis is usually good, with most patients having complete recovery within 2 years (54).

Isolated trauma to the plexus in the absence of a shoulder dislocation or burner is uncommon. Shoulder dislocation or burner usually occurs in conjunction with fractures of the humeral head/neck or the clavicle. A direct blow from a helmet or a significant impact distracting the head or shoulder can injure the plexus.

Thoracic outlet syndrome does not appear to have an increased incidence in athletes and is a relatively uncommon disorder, especially the neurogenic form. Athletes will usually report neurologic symptoms that correspond to the medial cord or lower trunk of the brachial plexus.

## ELBOW

The elbow is comprised of the distal humerus and proximal ulna and radius. The humeroulnar joint allows flexion and extension. The humeroradial articulation occurs between the capitulum of the humerus and head of the radius. The proximal radioulnar articulation (superior radioulnar joint) is a pivot joint allowing rotation of the radius about the ulna for pronation and supination.

### Tendinitis

The muscles (in descending order of frequency) most commonly involved in lateral epicondylitis are the extensor carpi radialis brevis and extensor digitorum communis; in medial epicondylitis are pronator teres, flexor carpi radialis, palmaris longus, flexor carpi ulnaris, and flexor digitorum superficialis. Posterior elbow tendonitis involves the triceps muscle. Tendinitis about the elbow appears to develop from overuse (demand greater than supply) or abnormal loading of the tendon. Nirschl and Pettrone noted that the histology of lateral epicondylitis (primarily affecting the extensor carpi radialis brevis) was “angiofibroblastic hyperplasia” and subsequently coined the term “angiofibroblastic tendinosis” (46). For the first time, it was theorized that this condition was a degenerative process and not inflammatory; in fact, no inflammatory cells were identified. In 1980 and 1981, they noted the same changes in medial and posterior epicondylitis, respectively. These authors feel that these conditions are primarily degenerative processes (55).

In lateral epicondylitis (aka. tennis elbow), pain is typically produced with palpation approximately 1 to 2 cm distal to the extensor origin. There is pain with resisted wrist extension and supination, and passive wrist flexion. Once diagnosed, the most important treatment aspect is to identify the offending behavior (e.g., poor tennis mechanics, repetitive job or recreational activity, etc.) and attempt to modify it. Restoration of motion and strength should not be forgotten as important components of the rehabilitation.

Medial epicondylitis is felt to occur from microtearing of the common flexor tendon’s origin of the medial epicondyle or

subsequent failed healing response that alters the normal tendon biomechanics (56). Initially, this develops as an inflammatory response, but can then develop into a degenerative process as noted above. This is common in throwing athletes and can occur in the trail arm of golfers (the so-called golfer’s elbow). Chronic valgus stress to the medial elbow can lead to laxity of the ulnar collateral ligament and instability of the elbow.

ROM of the elbow, including pronation and supination, varus and valgus stress testing, and an upper-limb neurologic examination, should be incorporated with the patient’s history for evaluation. Flexibility of the wrist flexors and extensors as well as strength testing at the wrist can clarify reasons for patients’ pathology.

### Neuropathies at the Elbow

The ulnar, median, and radial nerves are the three major nerves that traverse the elbow. The ulnar nerve lies posterior in the ulnar groove and is the most susceptible to injury. Additional physical exam maneuvers should be employed for further evaluation. With palpation of the ulnar nerve in the groove, one may be able to cause it to subluxate. Tinel’s sign produced by percussion over a nerve denotes membrane instability. The elbow hyperflexion test can place added tension to the nerve reproducing the patient’s symptoms. Care must be taken to avoid concomitant wrist flexion. With stress or stability test, traction of the nerve may occur causing provocation of symptoms.

Cubital tunnel syndrome is entrapment of the ulnar nerve in the cubital tunnel where the two heads of the flexor carpi ulnaris form a rooflike structure that overlies the ulnar nerve. It has been used more generally as a term indicating compression of the ulnar nerve in the region of the elbow. This may occur from “internal” compression by adjacent soft tissues or external compression on the nerve in the ulnar groove, or from repeated stretching by elbow overload. This can present with pain or paresthesias along the ulnar portion of the forearm with or without accompanying fourth- and fifth-digit symptoms.

The radial nerve innervates the triceps and anconeus in the arm and provides branches to innervate the brachioradialis and extensor carpi radialis longus, then transverse the elbow joint to the forearm. Once in the forearm, it splits into the superficial and deep branches. The deep branch is mainly motor, although noncutaneous sensory fibers also exist. It becomes the posterior interosseus nerve after its innervation of the extensor carpi radialis brevis and supinator. A lesion or entrapment of the posterior interosseus nerve must be considered in patients with presumed refractory lateral epicondylitis. Patients have lateral elbow aching localized to the region of the extensor origin or symptoms may be referred distally to the wrist. There can be reports of paresthesias in the lateral forearm or hand.

## WRIST AND HAND INJURIES IN SPORTS

The wrist is comprised of two rows of four bones each. The proximal row contains the scaphoid, lunate, triquetrum, and

pisiform, and the distal row includes the trapezium, trapezoid, capitate, and hamate.

Palpation of each of the carpal bones and the digits can be performed easily because there is little soft tissue covering them. The mobility and stability between the bones also can be tested for possible ligament injuries. The joints of the digits can be tested with volar/dorsal and varus/valgus forces to test for ligament compromise.

### Common Wrist Fractures

The most commonly fractured carpal bones are the scaphoid and triquetrum (57). Scaphoid fractures are often missed, and a high index of suspicion should be maintained with persistent radial wrist pain after trauma, even if initial x-rays are negative. The scaphoid and lunate are the bones most susceptible to avascular necrosis and should be monitored accordingly.

The wrist also includes the distal portions of the radius and ulna, as well as the distal radioulnar joint. A distal radius fracture is one of the most common injuries treated by orthopedists. Colles' fractures are radial metaphyseal injuries usually of low energy and do not involve the articular surface.

The thumb can sustain extraarticular and intraarticular fractures and crush injuries. Axial loading of the thumb can commonly cause a Bennett's or Rolando's fracture, which occurs at the base of the metacarpal.

With suspected fractures, excessive motion or force may worsen the injury and should be avoided. A detailed knowledge of the wrist anatomy is important to guide the palpation and development of a differential diagnosis. With continued symptoms, a high index of suspicion should be maintained because fractures can be missed on initial x-rays. As always, the neurovascular status should not be overlooked.

### Ligament Injuries of the Wrist

The most common carpal instability occurs between the scaphoid and lunate. Patients typically have a traumatic event with resultant dorsal- and radial-sided wrist pain and loss of motion with reduced grip strength. Physical examination should include palpation of the scapholunate junction and a scaphoid shift test, or Watson's test (58), which will result in pain and increased motion. This can be identified by stress x-ray with a clenched fist ulnar deviated view if standard views fail to demonstrate flexion of the scaphoid and extension of the lunate. The fist places tension across the scapholunate ligaments, and increased joint space is seen. If the images are difficult to interpret, comparison views to the contralateral limb can be obtained. The second most common ligament injury is a lunotriquetral tear. Examination should include palpation of the joint and a lunotriquetral shear test (58).

### Ligament Injuries of the Thumb

Gamekeeper's thumb or skier's thumb is a very common injury of the ulnar collateral ligament. When torn or attenuated, an athlete's key pinch grip is severely impaired. When evaluating this injury, one should keep in mind that complete tears can result in entrapment of the adductor aponeurosis in the

metacarpophalangeal (MCP) joint, or what is referred to as a Stener's lesion. This will impair healing and cause sustained laxity. A reverse gamekeeper's thumb refers to an injury of the radial collateral ligament and will not develop a Stener's lesion. On examination, one can stabilize the radial portion of the metacarpal phalangeal while applying a force distally to stress the ulnar collateral ligament (Fig. 53-6). A grade I causes pain and no increased motion, whereas a grade III causes no pain from the absence of an intact ligament and continued motion while stressing. A grade II demonstrates increased opening with pain on stressing. When stressing the joint, care must be taken to avoid overstretching the ligament and causing further injury. The thumb should be tested in extension and slight flexion to evaluate all fibers of the ligament (see Fig. 53-6).

### de Quervain's Stenosing Tenosynovitis

de Quervain's stenosing tenosynovitis is inflammation of the first dorsal compartment (abductor pollicis longus and extensor pollicis brevis [APL and EPB]) and can occur with overuse in sports in which equipment is gripped and the wrist ulnar deviated, such as golfing, fly fishing, and playing racquet sports. Radial wrist pain is noted with resisted thumb extension or palpation over first dorsal compartment, which should elicit the patient's symptoms. Many patients may have concomitant irritation of the superficial radial nerve, which partially overlies this area.

### The Triangular Fibrocartilage Complex

The triangular fibrocartilage complex can be a cause of ulnar-sided wrist pain, along with tendinitis, fracture, or impaction. The fibrocartilage begins at the distal radius, blending with the hyaline cartilage of the lunate fossa. It narrows toward

**FIGURE 53-6.** Skier's thumb examination: A valgus force is applied to the interphalangeal joint of the thumb to stress the ulnar collateral ligament.

the ulna, with deep fibers inserting into the fovea of the ulnar styloid. The cartilage thickens dorsally and palmarly, forming the radioulnar ligaments. There is a meniscal homologue from the distal ulna to the triquetrum, with an interval between the ulnotriquetral ligament known as the prestyloid recess (59). Understanding the anatomy guides palpation of the structures and development of a diagnosis. There exists little research on the natural history of these tears, which appear to do poorly with or without surgical intervention. It is unknown how many triangular fibrocartilage complex tears exist in asymptomatic persons. Shearing forces to entrap the tear or cause pain have been attempted with ulnar deviation and loading while pronating and supinating the hand. A positive test has been defined as a “pop” or “click” and not isolated ulnar wrist pain. The sensitivity and specificity of the test are unknown.

### Injuries to the Digits

Coach's finger or a jammed finger is most commonly a proximal interphalangeal dislocation reduced by the coach or athletic trainer. The dorsally directed dislocation is the most common, and volar plate injuries or fractures must be considered. If stable, it can be treated nonoperatively with splinting. Often this is an injury not mentioned to medical staff by the athlete and is self-reduced, but it can become stiff and painful if not treated appropriately.

Mallet finger is a rupture of the terminal extensor tendon of the distal phalanx causing loss of active extension. Active extension of the distal joint must be carefully evaluated to avoid missing this injury. This is usually caused by forced flexion of the distal phalangeal joint and can be caused by being hit on the end of the finger with a ball, such as a baseball or basketball.

Jersey finger is the avulsion of the flexor digitorum profundus from the distal phalanx. This occurs most commonly in the fourth finger (60). Usually, an athlete is attempting to tackle a player when his finger is caught in the jersey, and forced extension occurs against the contracting long flexor. Active flexion of the digit should be evaluated. Retraction of the tendon into the hand usually occurs unless stopped by an attached bone fragment.

Trigger fingers are thickening of the proximal portion of the flexor tendon sheath, which may develop from chronic irritation of the palmar surface of the metacarpal phalangeal joint by stick or racquet. The digit may become “stuck” and fixed in flexion until passively maneuvered because the thickened sheath becomes hung up at the A-1 pulley. This “sticking” can usually be demonstrated by the patient on exam. If it is unclear, one can have the patient actively flex the digit and while palpating the volar MCP region, passively extend the digit. One usually feels a nodule, which “pops” during extension.

### Nerves of the Wrist and Hand

The wrist and hand region includes the radial, median, and ulnar nerves. The superficial radial sensory nerve is superficial

over the distal lateral radius and vulnerable to injury via contusion. It can also be caught between the brachioradials and extensor carpi radialis brevis with repetitive pronation/supination. The median nerve can become contused, but more commonly is irritated by repetitive motion of either the wrist or flexor tendons. Athletes who grip equipment as part of their sport, including cycling, baseball, and racquet sports, should consider wearing gloves. The ulnar nerve can become contused or compressed at Guyon's canal and is an additional reason for athletes to wear protective hand gear.

Strength and sensation should be tested. One should be mindful of testing different sensory modalities accurately, including pinprick, light touch (avoiding light pressure), two-point discrimination, and temperature.

## DIFFERENTIAL DIAGNOSIS FOR LOW BACK PAIN IN ATHLETES

### Lumbar Disc Injury

The intervertebral disc is a hydrodynamic elastic structure that has two components: the annulus fibrosus and nucleus pulposus. In early life, until the later thirties, blood vessels passing to the end plate are progressively obliterated, with most nutrition provided for via the process of imbibition, in which compression and distraction force nutrients into the disc. The annulus fibrosus is composed of layered sheets of collagen fiber, with the individual fibers enhancing overall mechanical efficiency. The nucleus pulposus is composed of a homogenous mucopolysaccharide matrix containing a network of fine protein-based fibrils. Biomechanically, intrinsic disc pressure functions to separate vertebral end plates and maintain tension within annular fibers. Flexion and extension forces are well tolerated by the annulus, whereas the addition of rotational forces causes excessive stress to the annulus leading to failure.

Lumbar disc injury is a relatively uncommon injury in the young competitive athlete (61). Micheli and Wood noted that 11% of adolescents as compared with 48% of adults with low back pain had evidence for disc injury (62). Although uncommon, there may be more significant changes to the structure of the disc in athletes as compared with nonathletes. Sward et al. noted disc degeneration in 75% of male gymnasts as compared with 31% in an age-matched group of nonathletes (63). Various sports have been evaluated in regard to the potential increased risk of disc herniation. Mundt et al. found only a weak association between bowling and herniation of the lumbar disc, with no significant association found in other sports, including baseball, softball, golf, swimming, diving, weightlifting, or racquet sports (64).

### Lumbar Facet Syndrome

The lumbar zygapophyseal joints are true synovial joints and are subject to inflammation. It is of key importance to understand the anatomy of these joints, as it will clearly influence diagnostic and treatment decisions (65). The lumbar facet

joints maintain a sagittal orientation from L1 to L4, with a more coronal orientation encountered at L5 to S1. These joints are innervated by the posterior primary ramus, which supplies at least two zygapophyseal joints, with each joint receiving innervation from at least two spinal levels. The joints allow between 2 and 3 degrees of rotation at each segment within the lumbar spine and account for between 12% and 24% of compressive load, the remainder of which is absorbed by the intervertebral disc. The amount of compressive load increases as the intervertebral disc height decreases, such as is seen with degenerative disc disease. The facet syndrome may thus result from degeneration of the disc or the joint itself, positional overload such as may be seen with any repetitive overuse injury and secondary to trauma (66,67).

The athlete often describes a sudden flexion/extension maneuver often combined with rotation/side bending as the precipitating event. Lumbar facet syndrome commonly occurs in football, volleyball, gymnastics, figure skating, golf, and tennis, in which end-range sagittal and transverse plane motions are combined. No significant research has been performed to identify the true incidence and prevalence of facet syndrome, which is most likely secondary to the difficulty in obtaining reliable objective measures.

### Lumbar Spondylolysis/Spondylolisthesis

Spondylolysis or fracture of the pars interarticularis can be related to an acute traumatic event or an overuse phenomenon causing stress fracture (68). Micheli and Wood reported spondylolysis as the final diagnosis of 47% of adolescents between the ages of 12 and 18 years presenting with reports of low back pain (62). Sports that require repetitive hyperextension will more commonly predispose to the development of a pars fracture. Rossi noted that 63% of divers, 36% of weightlifters, 33% of wrestlers, and 32% of gymnasts had evidence for spondylolysis as compared with 5% of the general population (Figs. 53-7 and 53-8) (69).

Spondylolisthesis is defined by a forward or backward subluxation of one vertebrae on another. There are several types of spondylolisthesis: the isthmic type has an anatomic defect in the pars interarticularis, dysplastic types have structurally inadequate posterior elements, degenerative types are the result of significant degenerative changes of the zygapophyseal joints and deficient supporting ligaments, traumatic types are the result of fracture of the posterior elements other than the pars, and pathologic types are the result of metabolic, malignant, or infectious disease (70). The Meyerding classification system separates slippages into 25% intervals, with a grade I defined by a 0% to 25% slip, grade II with a 26% to 50% slip, grade III with a 51% to 75% slip, and grade IV with a slip between 76% and 100% (71). Spondylolisthesis is an uncommon occurrence in the competitive athlete and is most likely secondary to superior dynamic muscular stabilization and skeletal maturity. Wiltse et al. noted its occurrence in skeletally immature adolescent athletes between the ages of 9 and 14, and it was rarely seen in athletes above this age range (71).

### Sacroiliac Joint Dysfunction

The sacroiliac joints are weight-bearing joints between the articular surfaces of the sacrum and ilium, which are located on the lateral surface of the sacrum. They are part synovial joint and part syndesmosis, with the synovial portion being the anterior and inferior one third of the joint (72). There is hyaline cartilage on the sacral side and fibrocartilage on the ilial side. There are no muscles that directly control movement of the sacroiliac joints, but many indirectly affect movement. Sacroiliac joint movement is mainly passive in response to the action of surrounding muscles. The psoas and piriformis muscles pass anterior to the sacroiliac joints, and imbalance of these muscles in particular may affect sacroiliac joint function. Imbalance in the length and strength of the piriformis strongly influences movement of the sacrum. Sacroiliac joint dysfunction occurs when there is an alteration of the structural or positional relationship between the sacrum and a normally positioned ilium (73). The sacroiliac joint plays a small but significant role in the cause of low back and buttock pain,

**FIGURE 53-7.** A lateral lumbar roentgenogram of the lumbar spine demonstrating a lucency of the pars interarticularis, which represents a fracture.

**FIGURE 53-8.** An oblique lumbar roentgenogram of the lumbar spine demonstrating a lucency of the neck of the “Scottie dog,” which represents a fracture of the pars interarticularis.

although the true incidence is unknown. It has been reported to occur in elite cross-country skiers, rowers, and gymnasts (74–76). It is a true synovial joint with extensive innervation from the lumbosacral region, accounting for the difficulty differentiating sacroiliac joint dysfunction from that of surrounding structures. Various medical conditions, such as rheumatologic disorders, infection, and neoplasms, may also affect the joint, and it is extremely important for the sports physician to rule out the possibility of sacral stress fracture. Johnson et al. demonstrated sacral stress fractures in five collegiate athletes presenting with pain over the region of the sacroiliac joint (77). It is therefore prudent to perform further diagnostic workup in those subjects diagnosed with sacroiliac dysfunction who have a history of or risk factors for stress fracture or remain refractory to conservative care.

## COMMON LOWER EXTREMITY INJURIES IN SPORTS

### Hip

The hip can be injured in a variety of sports, either from direct trauma or musculotendinous overload. In either case, the athlete is often greatly impaired in sport participation as a result

of significant alterations in gait. It is important to quickly determine the etiology of the problem, allow for a period of rest, and maintain strength and flexibility as these injuries heal. Almost all respond to the previously outlined course of functional rehabilitation.

### Hip Pointer

The “hip pointer” injury is a direct blow to the pelvic brim or hip region, which results in a contusion to the soft tissues and often the underlying bone. It is relatively common in sports such as football and hockey, where there are many collisions (both player to player as well as contact between the player and the field or arena). Common areas include the greater trochanter and iliac crest. The contact can result in hematoma formation, but often there is little visible swelling or ecchymosis. There is, however, a significant amount of pain and focal tenderness that is due to bony contusion and periosteal irritation. The athlete usually has difficulty with quick bursts of running and with any contact to the area.

The diagnosis is made by the above history or on field observation. On examination, it is important to note full ROM of the hip and the knee. If there is a great deal of pain with passive ROM, then x-rays should be obtained to rule out any significant bony pathology. For most injuries, imaging studies are not necessary. In cases of significant soft-tissue swelling, additional imaging such as CT or MRI may be indicated.

The treatment requires frequent and repeated icing, active ROM, and a period of rest until gait can be normalized. In a very painful hip, crutches with weight bearing as tolerated may be necessary for pain control and to unload the hip. NSAIDs can be helpful in the very early period to assist with pain control and inflammation but can generally be discontinued in less than a week. Once an athlete has no pain at rest or with running and jumping activities and minimal pain on palpation, he or she can be returned to play, usually with protective padding. Appropriate padding over the area is important to protect the area from recurrent injury. This can be coordinated with the trainer and generally consists of soft foam over the area or doughnut cutouts surrounding the area. Most of these injuries do not result in long-term sequelae.

### Hip Flexor Strain

Hip flexor strains are commonly seen in sprinting as well as in other sports, such as soccer, baseball, and football. They occur as a result of an eccentric overload of the psoas muscle or as the athlete attempts to flex the fully extended hip, such as in hurdling. Most athletes are unable to continue to run, and for most sports, this means discontinuing participation. The examination is straightforward, with tenderness to palpation over the area and with resisted hip flexion and passive hip extension. ROM may also be painful; therefore, the majority of these injuries require plain x-rays of the hip (usually an anteroposterior and frog-leg lateral view) to exclude bony injury. This is particularly important in the adolescent or skeletally immature athlete, as injury to the apophyseal plate can commonly occur.

These various avulsions, whether in the adult or adolescent athlete, can also be treated nonoperatively.

Treatment of hip flexor strains and/or avulsions consists of protected weight bearing when there is a significantly antalgic gait, aggressive icing, and gentle active ROM as soon as possible. Strengthening exercises of the lower extremities should be avoided until the gait is nonantalgic and ROM is full and pain free. Then the athlete should be progressed through an aggressive strengthening consisting of both open and closed kinetic exercises. Eccentric and plyometric training should be added when the athlete is ready and can be invaluable in preventing recurrent injuries that are common.

### Greater Trochanteric Bursitis

Greater trochanteric bursitis generally occurs secondary to repeated irritation of the bursa, or less commonly from direct trauma. Traumatic inflammation of the bursa is seen in collision sports, such as football and hockey, and at times in soccer and baseball after sliding hard into a base or hitting the ground after diving for a ball. Repeated irritation usually occurs secondary to other biomechanical abnormalities such as a tight iliotibial band (ITB) and/or weakness of the hip abductors. The athlete reports an aching pain along the lateral aspect of the hip that is worse with running and jumping and any contact on the area, including laying on the affected side at night. Physical examination will demonstrate relative weakness of the hip abductors on the affected side, a tight ITB on Ober testing, and significant pain with direct palpation over the bursa.

Treatment consists of icing, NSAIDs, and stretching of the ITB and strengthening of the hip musculature with attention to the hip abductors. In refractory cases, injection of a corticosteroid into the bursa can be very helpful in progressing the rehabilitation process. Ultrasound is not indicated in acute cases but can be helpful in chronic recurrent cases to assist with stretching the proximal ITB.

### Knee

Knee injuries are common in almost all sports, particularly those that require running, jumping and pivoting, and cutting. In addition, contact and collision sports often place the knee joint at risk for injury. It is important to understand the anatomy and biomechanics of the knee joint and how the injury can affect the various structures of the knee, including the patellofemoral joint, tibiofemoral joint, the two menisci, and the four primary ligaments (ACL, posterior cruciate ligament [PCL], lateral collateral ligament [LCL], and medial collateral ligament [MCL]).

### Patellofemoral Syndrome

Anterior knee pain, also referred to as patellofemoral syndrome, is one of the most commonly encountered problems of the knee seen in a sports medicine practice. The incidence of this syndrome is reported to be as high as one in four in the general population (78). It also occurs with an incidence of 19% after ACL reconstruction (79).

Many theories exist regarding the etiology of the patellofemoral syndrome. Goodfellow et al. (80) described a failure

of energy absorption by the articular cartilage causing increased patellar subchondral bone pressure. Ficat and Hungerford (81) placed emphasis on lateral malalignment causing hyperpressure of the lateral patellofemoral compartment and hypopressure on the medial patellofemoral joint. Laurin et al. (82) radiographically confirmed that early signs of chondromalacia appeared first on the medial patellar facet, with osteoarthritis more advanced on the lateral patellar facet. Abnormal lateral tracking of the patella remains the most common theory at the present time. A number of causative factors are linked to patellofemoral syndrome, with weakness/tightness of muscle groups, bony abnormalities, and malalignment of the lower extremity being the main ones (81).

Vastus medialis obliquus (VMO) insufficiency is often cited as one of the abnormalities resulting in patellofemoral syndrome. The function of the VMO is to help maintain proper patella tracking during extension of the knee. It is the only dynamic medial stabilizer and, if weak, it allows lateral tracking. The fibers of the VMO originate from the tendon of the adductor magnus and vastus medialis. This becomes an important point during treatment. Mariani and Caruso (83) found a decrease in VMO activity compared with vastus lateralis activity in those with patellar subluxation. Voight and Wieder (84) showed an increased speed of firing of vastus lateralis in those with PFS. The exact importance of VMO firing remains somewhat controversial.

The Q (or quadriceps)-angle is the angle formed by the intersection of lines drawn from the bisection of a line from anterior superior iliac spine (ASIS) to the superior patella and a second line from the inferior patella to the tibial tubercle. It is increased by increased femoral anteversion, external tibial torsion, increased pronation, lateral displacement of the tibial tubercle, and any lateral rotation of the patella. The upper limit of normal is greater than 12 degrees in men and greater than 18 degrees in women (85). Tightness of various soft-tissue structures about the knee can result in a functional increase in the Q-angle, which results in abnormal kinematics which affect patellar tracking, resulting in patellofemoral pain.

ITB tightness is felt to result in abnormal patellar tracking as its distal-most fibers insert on the lateral patella, exerting a lateral pull during knee flexion. Hamstring tightness also contributes to patellofemoral syndrome as it increases the patellofemoral joint reaction force in stance. Rectus femoris tightness increases anterior compressive force and has a net vector lateral pull on the patella. Gastrocnemius tightness causes a decrease in ankle dorsiflexion, with a resultant compensatory pronation of the foot, via the subtalar joint, which results in an increase in the Q-angle and consequently, a lateral patellar deviation. Hyperpronation results in internal rotation of the leg and femur, also increasing the Q-angle, and results in malalignment of the patella.

The treatment for patellofemoral syndrome first lies in a thorough analysis of contributing factors. Biomechanical abnormalities should be diagnosed and addressed. Acutely, pain control is addressed with ice, NSAIDs, and occasionally, electrical stimulation. Patients should avoid activities causing

pain, which include kneeling, excessive stair climbing, and prolonged sitting. Patients should be given appropriate shoe orthotics if hyperpronation is an issue. Proper stretching of gastrocnemius, hamstrings, and ITB is essential in treatment. McConnell taping can be done to improve the positioning and tracking of the patella and to facilitate an aggressive stretching and strengthening program. Patients are generally taught how to tape themselves until their symptoms resolve (86). VMO strengthening via straight leg raising with adduction, EMG biofeedback, and squats with abduction pillow (so that squat is performed with adduction to strengthen VMO) are carefully reviewed with the athlete to ensure proper technique and VMO activation. Athletes are also instructed on patella mobilization techniques (particularly medial and inferior glides) to improve proper tracking. For athletes with significant pes planus or hyperpronation, an in-shoe orthotic is generally prescribed to help normalize the overall lower extremity biomechanics. The results of treatment for patellofemoral syndrome are generally quite good. Ingersol and Knight (87), using EMG biofeedback for VMO strengthening, demonstrated radiographically improved patellar tracking. Doucette and Goble (88), treating patients with a program of VMO strengthening and ITB and hamstring stretching, demonstrated good results in 84% of patients. There have been many other treatments that have demonstrated efficacy as well; therefore, the specifics of treatment remain controversial. The importance of good motor control and tracking of the patella does appear to be well accepted.

### Medial and Lateral Collateral Ligament Sprains

The collateral ligaments are important for maintaining medial-lateral stability of the knee joint. They are susceptible to injury from direct trauma, producing varus (LCL) and valgus (MCL) loads.

The MCL is the most commonly injured knee ligament in sports. It occurs from a valgus force to the knee joint that stretches or tears the ligament. It can also be injured in association with other structures of the knee, including the ACL, the medial meniscus, and the joint capsule. It is important to rule out injury of any of these associated structures, as the rehabilitation will be different. Isolated, complete tears of the MCL can be successfully managed nonoperatively at all levels of sport participation and should be considered the state-of-the-art treatment for this injury (89). Once again, the previously described program is applied. The knee should be protected by a double upright hinged knee brace, which initially can be used in conjunction with crutches until a normal gait pattern is established. This same brace can then be used as a functional knee brace for returning to sport. It is important to promote active ROM of the knee. This can be done on an exercise bike, which will promote full ROM without causing medial-lateral stress to the MCL. Strengthening should also progress along with the protection, ROM phases moving as quickly as possible to closed kinetic chain strengthening, which are more functional. Once again, plyometric and power-strengthening issues should be addressed once there is no pain, full ROM,

and symmetric strength. Serial examinations should be used to readdress the stability of the MCL on valgus stress testing. This should demonstrate decreasing pain and improved stability. Return-to-sport criteria require the athlete to be pain free and have full ROM, normal strength, no effusion, no pain, and minimal to no laxity on valgus stress testing. Once again, with a complete MCL tear, knee bracing would be recommended for 6 to 9 months (usually for the remainder of the sport season).

Although isolated LCL sprains are less common, they too can be managed nonoperatively; however, great care must be taken to rule out injury to other structures, such as the posterior lateral corner, PCL, and ACL. If there is any question regarding the integrity of these structures, additional imaging and referral to an orthopedic surgeon specializing in sports medicine are recommended.

### Anterior and Posterior Cruciate Ligament Injury

The cruciate ligaments cross within the knee joint, providing predominantly anterior and posterior stability, along with lateral rotatory stability to the knee joint. ACL injuries most commonly occur following a hyperextension injury or from a significant valgus force of blow to the knee. O'Donohue described the "unhappy triad" following a valgus injury to the MCL, ACL, and medial meniscus, although lateral meniscal tears are also quite common (90,91). In general, ACL injuries do not heal, although there are rare reports of spontaneous healing, especially injuries at the attachment to the femur (92,93).

In ACL injuries, patients often describe hearing or feeling a "pop" with an unstable sensation of the knee. If chronic, give-way episodes of the knee are common with rotatory activity, such as pivoting. An effusion (hemarthrosis) usually develops rapidly and is generally quite obvious on physical examination as a result of the significant vascularity of the ACL. On examination, a positive anterior drawer and Lachman test should be noted. Other structures about the knee should also be carefully examined. If the findings on examination are unclear, then additional imaging (usually MRI) of the knee is indicated.

PCL injuries generally occur with a posterior force to a bent knee, such as after being tackled or receiving a blow with the knee in 90 degrees of flexion as can occur with a dashboard injury during a motor vehicle accident. There usually is little swelling, and often the athlete may attempt to play. On examination, there is a positive posterior drawer sign, which is the most sensitive examination test for a PCL injury (94). Once again, care must be taken to avoid missing injuries to the lateral structures of the knee.

Nonoperative treatment with a stepwise approach as previously described can be tried for both ACL and PCL injuries; however, for a young athlete who wishes to continue with high-demand sports (i.e., jumping/twisting/pivoting-type sports), then ACL reconstruction is recommended. For those who attempt a nonoperative treatment course, the results can be favorable, particularly if there is a strong focus on the later stages of strengthening and proprioceptive training, along

with some type of functional bracing. A 15-year follow-up study by Ageberg and colleagues revealed that good functional performance and knee muscle strength can be achieved and maintained over time in patients with ACL tears undergoing aggressive and early functional rehabilitation and not reconstructive surgery (95). Functional bracing is actually considered both for surgically repaired and nonsurgically repaired ACLs. A 15- to 20-degree extension stop on these braces should be strongly considered, as the authors believe that this accentuates the proprioceptive aspect of the brace.

Isolated PCL injuries have been found to do quite well. A functional stepwise approach works very well with a bias toward greater quadriceps strength and closed kinetic training. We have not found bracing to be necessary or helpful.

### ACL Injury Prevention

ACL injury is common in sports as has been previously mentioned. As female participation in athletics has increased since the inception of Title IX, there has been a dramatic rise in the rate of these injuries (96). Furthermore, we are learning that the long-term morbidity is not favorable. A literature review on the topic by Lohmander and colleagues suggests that 10 to 20 years after an ACL tear, osteoarthritis will develop in the knee, regardless of whether the ACL was surgically repaired or not (97). Therefore, prevention of ACL injuries is extremely important not only for the immediate consequences of an ACL tear on the athlete, but also because of the long-term structural damage that can occur in the knee at an early age for most of these athletes as they progress into their 30s and 40s.

Studies have shed light and understanding into the biomechanics of ACL injuries in young female athletes. These studies have analyzed the mechanics that these athletes use when the knee is placed in positions known to cause ACL tears, such as landing from a jump, sharp cutting, or decelerating. These positions often place the knee in flexion and internal tibiofemoral rotation. Hewett and his colleagues have described their theory that dynamic knee instability is caused by three factors: ligament dominance, quadriceps dominance, and leg dominance (96).

Ligament dominance refers to the fact that females tend to depend on their ACL for joint control, rather than on their muscles and on their neuromuscular firing and recruitment, when compared to their male counterparts. Quadriceps dominance refers to young female athletes having significantly weaker hamstrings than quadriceps. Building on the known observation that at angles greater than 45 degrees, the quads act as antagonists to the ACL, deep knee flexion and strengthening of the knee flexors (i.e., the hamstrings) have been proposed as a protective mechanism for the joint (96).

These researchers have therefore devised a dynamic neuromuscular analysis and training program for the prevention of ACL injuries, in particular in the female athletic population. It is a program that incorporates biomechanics, plyometrics, core stability, and strength training of the hamstrings to develop adequate neuromuscular adaptation for the knee

and to enhance kinetic chain control and balance. The goal of this program is to analyze and correct the biomechanical that are made by these young female athletes when the knee is in ACL-stressing positions. By correcting such errors early in the life of these athletes, they will be protected from injury later in their athletic endeavors (96,98). The incorporation of such programs into communities could have a tremendous impact on reduction of ACL injury rates in the female athletic population.

### Meniscal Tears

The menisci serve as shock absorbers and force dissipaters to protect the knee joint. They can be injured in isolation or in conjunction with other structures, such as the collateral ligaments, ACL, etc. These injuries can be from either a direct blow to the knee or a twisting type injury, as the menisci are susceptible to compression/rotation forces. Degenerative meniscal tears in the older athlete may become symptomatic following a prolonged period of knee flexion.

Patients will generally report swelling or “tightness” within the knee from the associated synovitis that occurs, and bleeding in the younger athlete if there is injury to the vascular portion of the meniscus. There can be mechanical symptoms such as catching or locking with an associated or intermittent clicking. Symptoms are generally increased with knee flexion and are often localized to the joint line.

On examination, there is usually a small to moderate effusion, with pain on flexion and on palpation of the joint line over the side of the injured meniscus. As noted above, McMurray test, while very specific, has a low sensitivity and therefore should not be used as the determinant of meniscal injury in isolation (99).

Many meniscal tears can be treated conservatively with a combination of relative rest, vigorous icing, and NSAIDs initially, followed by a course of physical therapy with restoration of motion and an aggressive strengthening program stressing closed kinetic-type exercises. If the effusion persists in spite of compression and icing, aspiration and injection with a corticosteroid can be very helpful in decreasing the reactive inflammatory response, which inhibits the normal muscle firing of the knee. In those patients with a locked knee or severe mechanical symptoms and those unresponsive to a 2- to 3-month course of physical therapy, arthroscopic treatment with either resection of the unstable portion or repair (if possible) has been very effective.

### Ankle

#### Achilles Tendinitis

Achilles tendinitis has been described in any sport requiring running or rapid changes in direction, such as in racquet sports such as tennis or badminton (100–102). It typically begins as an inflammatory reaction around the Achilles tendon/paratenon. The paratenon surrounds the tendon but is not a true synovial sheath. If not treated, microtears, mucoid degeneration, longitudinal fissuring, and scarring develop. Running is the most commonly associated activity, associated

with 53% of those cases studied by Kannus et al. (103). The etiology is multifactorial, with overuse being the most common cause (104). It is also associated with a rapid increase in mileage, increased interval training, and running downhill or sloping hills. Numerous biomechanical problems are correlated with Achilles tendinitis, and a thorough biomechanical analysis is necessary in resistant cases. Treatment consists of decreasing inflammation, followed by aggressive stretching of the gastrocnemius/soleus complex. Strengthening should be initiated in concert with stretching to improve the ability of the tendon to withstand repetitive changes in length and load. Eccentric strengthening is the most important aspect of strengthening and is based on three parameters: length, load, and speed (105). Stretching helps to increase the length of the muscle tendon unit and reduce strain with joint movement (106). Increasing load to myotendon unit helps to increase its tensile strength. Finally, increasing speed of contraction helps to increase force of contraction.

### Ankle Sprains

Inversion ankle sprains are the most common traumatic injuries encountered in sports that require running or jumping, such as football, basketball, tennis, soccer, and gymnastics. Deltoid ligament and syndesmotic ankle sprains occur much less commonly and are usually associated with more significant trauma to the ankle. They have been well described in football and soccer (107–109).

As noted above, the most common injuries to the ankle involve the lateral ligament complex, consisting of the anterior talofibular, calcaneofibular, and posterior talofibular ligaments. A grade I ankle sprain involves a mild sprain of the anterior talofibular with a negative ankle drawer and talar tilt test. A grade II sprain involves disruption of the anterior talofibular with sprain of the calcaneofibular, with a positive ankle drawer and a negative talar tilt test, whereas a grade III ankle sprain involves disruption of the lateral ligament complex with both positive ankle drawer and talar tilt tests. The careful clinician must completely evaluate the individual with ankle sprain to rule out concomitant fracture of the fibula or fifth metatarsal, which may occur at the time of inversion injury. The Ottawa ankle rules have been used to determine when radiologic assessment is necessary in the face of inversion ankle injury. Some positive indicators for testing include difficulty bearing weight and tenderness about the medial or lateral malleolus or fifth metatarsal.

Deltoid ligament injuries constitute only 5% of ankle injuries and result from eversion injury to the ankle (110). These injuries may occur concomitantly with inversion ankle sprains; therefore, the medial aspect of the ankle must be inspected with any significant inversion sprain. The majority of isolated injuries to the deltoid ligament are mild, with more significant injuries often associated with injury to the anterior and posterior tibiofibular ligaments, along with diastasis of the syndesmosis. Syndesmotic ankle sprains are more common than significant deltoid ligament sprains, which may relate to the overall tensile strength of the deltoid ligament complex.

They may be missed if a comprehensive evaluation is not performed, including palpation in or about the region of the anterior tibiofibular ligament or manual loading of the ankle mortise. Evaluation of the individual with deltoid ligament or syndesmotic sprain must also include a careful assessment of the fibula to rule out distal or proximal (Maisonneuve's) fracture. Syndesmotic ankle sprains can be a significant source of disability in the competitive athlete with a significantly prolonged recovery time as compared with isolated inversion ankle sprains (109).

Treatment of ankle sprains involves the principles of pain control through the use of ice and anti-inflammatory medication, relative rest, and early mobilization. In concert with early mobilization, the individual with an ankle sprain must be instructed in balance and proprioceptive exercises with progression toward strengthening of the musculature of the foot and ankle. Return to sport may depend on satisfactory completion of a rehabilitation program, compliance with a home exercise program, and the use of taping or bracing. More significant ankle inversion (grade III) or deltoid ligament sprains may require surgical intervention if chronic instability results in residual functional deficits.

### Foot

#### Metatarsophalangeal Sprain ("Turf Toe")

Injury to the metatarsophalangeal joint generally occurs with hyperextension injuries of the great toe in sports such as football and soccer. It has been termed "turf toe" because of the unforgiving and stiff surface of synthetic surfaces. In addition to hyperextension, there are often added forces, such as tacklers or other players falling on the injured athlete. This is associated with localized pain at the metatarsophalangeal joint and pain with weight bearing, but especially during push off in running. The examination can demonstrate some localized tenderness with some localized swelling and decreased or painful ROM. In recurrent injuries, loss of motion and degenerative changes about the joint may occur. The treatment consists of the PRICE regimen, with taping techniques to limit motion at the joint. A long rigid shoe orthotic may assist in decreasing force across the joint to facilitate return to play. This can be a very disabling injury, requiring several weeks of rest before return can be accomplished. Occasionally, corticosteroid injection is necessary to control pain and inflammation of the joint and to facilitate a progressive rehabilitation program.

#### Plantar Fasciitis

The plantar fascia runs across the medial aspect of the foot from the medial calcaneus to the metatarsals to maintain the medial arch of the foot. A sudden loading of the feet can injure it, but more often it is inflamed and irritated insidiously by repeated overload. It can occur in both a pes planus foot and a pes cavus foot. The exact cause remains obscure, but it does appear that both muscular weakness and soft-tissue tightness play an important role. The symptoms are generally that of insidious onset of heel and plantar foot pain that is worse when

first rising in the morning or after a period of inactivity such as sitting. It can also increase after the end of a competition or practice or at the end of the day.

On examination, there is usually focal tenderness at the origin of the plantar fascia at the medial calcaneus and along the plantar arch. Pain can be elicited by hyperdorsiflexion of the great toe with palpation along the plantar fascia. There is usually associated tightness of the gastrocnemius complex and weakness of the soleus and possibly the tibialis posterior and tibialis anterior as well. Plain x-rays are often obtained and may reveal a tractional calcaneal spur that should not be interpreted as the cause of the symptoms but rather as an additional sign of overload of the plantar fascia. In addition, these spurs are often noted on the asymptomatic foot. Therefore, plain x-rays are not necessary for most patients who present with plantar fascia pain.

Treatment includes aggressive stretching and at times a night splint to produce a passive prolonged stretch of the tissues. Strengthening of the gastrocnemius, tibial, and foot intrinsic muscles helps to restore dynamic stability of the arch and foot and ankle joints. Patients with significant biomechanical abnormalities of the foot may benefit from a custom orthotic. The role and timing of corticosteroid injection are not clear. There is anecdotal evidence that they can be very helpful, but at what point and how often they should be injected is not clear (111–114). Surgical release of the plantar fascia is rarely necessary but can be helpful in recalcitrant cases (115,116).

### Midfoot Sprain

It is important for the sports medicine physician to be aware of midfoot sprains as they can be easily overlooked. The injury occurs with an awkward landing of the forefoot, usually in inversion. This can appear as a simple ankle sprain, and therefore the injury can be initially missed. On careful examination, the tenderness to palpation is localized to the dorsal-medial midfoot. Occasionally, there is swelling and ecchymosis in the area. With a varus stress to the foot, pain can be elicited as well. Most of these athletes are unable to even walk without an antalgic gait pattern. It is important to get plain x-rays of the foot and note any widening of the first and second metatarsal rays. Widening of greater than 5 mm is unstable and requires surgical fixation. If there is no significant widening on x-rays, 4 to 6 weeks of immobilization in plantar flexion and supination will allow for healing. The athlete should then progress through a functional rehabilitation program. As the injury heals, it is important to maintain aerobic conditioning of the athlete. For mild sprains, icing, wrapping, and crutch ambulation are used until the athlete can bear weight without any pain. This allows for maintaining strength and ROM as the tissue heals.

### CONCLUSION

The physiatrist is the ideal specialist to provide and coordinate care for injured athletes at all levels of competition. The team approach provides the best method of maximizing

an athlete's recovery from an injury. This chapter presents an overview on the basic principles of functional rehabilitation and some common injuries encountered when treating athletes.

# Physical Activity for People with Disabilities

Several studies have reported that people with disabilities are more likely to be sedentary (1,2), have health problems (3), and experience substantially more barriers to physical activity participation compared to the general population (4–6). This increases the likelihood that, as they age, they will have greater difficulty maintaining their ability to work, participating in recreational activities, performing self-care activities (7,8), and engaging in various activities in their community (9). The subsequent physical limitations that many people with disabilities experience may not be entirely associated with the primary effects of the disability, and some or much of the limitations may be related to the effects of disuse and deconditioning (10,11).

Improving health and function in people with disabilities has the potential to facilitate greater levels of participation in all aspects of society, including work, leisure, and recreation; reduce or mitigate secondary conditions (12); and achieve a higher satisfaction with life (13). An important first step in this process is for clinicians and health professionals to find effective ways to identify and remove the many barriers to participation that people with disabilities encounter when attempting to become physically active or increase their current levels of physical activity.

The focus of this chapter is to guide health care professionals in their efforts to increase physical activity in patients or clients with disabilities. The first section discusses how community-based physical activity programs can be used as a mechanism for transitioning patients/clients from rehabilitation to self-maintenance of health and function across the life span. Within this section is a discussion of an approach to promote physical activity in people with disabilities, which includes tailoring physical activity for a patient/client and a model for systematically prescribing physical activity for individuals with physical disabilities. The second section focuses on specific types of recreation, fitness, and sports activities that individuals with disabilities can engage in and identifies appropriate community-based resources.

## TRANSITIONING FROM REHABILITATION TO COMMUNITY-BASED PHYSICAL ACTIVITY

While most individuals who are recovering from a serious injury or accident will receive a certain amount of rehabilitation, the gains in health and function are often lost after the

person returns home if he/she does not continue some type of home- or community-based physical activity program (14,15). Most rehabilitation is limited to the subacute period and is designed to restore or improve the most critical functional skills needed to assist the person in performing BADL (basic activities of daily living) and/or IADL (instrumental activities of daily living) (15). Once the person returns home, much of the responsibility for continuing to perform the recommended rehabilitative exercises is left to the individual and/or his or her caregiver. Figure 54-1 provides a conceptual illustration of what often occurs after an injury, accident, or onset of a new health condition that leads to a progressive decline in health and function. Typically, an individual receives a few to several days of rehabilitation in a hospital setting or outpatient facility, though this varies according to the injury. Individuals with more severe disabilities (i.e., spinal cord injury) receive longer hospital stays. Significant progress is often made as a result of intensive rehabilitation and the natural phase of recovery. But after the person returns home to what is often a considerable alteration in health, function, and lifestyle, there is, theoretically, a gradual decline in health and function resulting from physical inactivity. A primary goal of every rehabilitation program should be to increase physical activity postrehab to avoid a state of severe deconditioning that could impose serious limitations in performing BADL and IADL. In some ways, the key to a successful rehabilitation program is identifying effective strategies that can support individuals in participating in some form of regular physical activity after they are no longer receiving therapy. People with disabilities who reported a higher level of physical activity also indicated a higher level of community reintegration compared to participants who described their physical activity as low or inactive (16,17).

## Tailoring Physical Activity to Meet the Unique Needs of the Patient/Client

Tailoring physical activity programs that recognize the unique circumstances surrounding each individual is an important aspect of prescribing physical activity programs that have a greater likelihood of successful initiation and adherence (18). Research on physical activity indicates that generic programs not targeted to the needs of any particular end user are far less likely to result in long-term maintenance of health-promoting behaviors (19,20). By assessing a combination of factors,

**FIGURE 54-1.** Getting beyond rehabilitation and transitioning people with disabilities into community-based physical activity.

including the person's motivational level (readiness to change), physical activity profile, health and mobility limitations, and barriers to participation, a program can be developed that meets each person's specific needs, interests, and circumstances. Thus, physical activity recommendations for people with disabilities may be more effective if they are individually and culturally appealing and are implemented in a setting of the individual's own choosing. This includes establishing realistic, achievable goals to meet the person's needs, while also finding solutions for the barriers to participation that frustrate even the most enthusiastic participant. The program also has to be dynamic (i.e., interesting, enjoyable) and have the opportunity to change frequently to accommodate changes in the life of the participant (i.e., boredom, getting a new job, experiencing some pain performing certain types of exercises, etc.). So many programs fail because the individual or his or her environment changes and the program is no longer interesting or challenging, or the environment changes and the person no longer has access to the same resources needed to participate in the program or activity.

### PEP Intervention Model

An example of an online resource that can assist rehabilitation professionals in providing more tailored physical activity recommendations to their patients/clients as they transition from in-patient rehabilitation to community-based activities is the Personalized Exercise Program (PEP). The PEP intervention model (shown in Fig. 54-2) begins with problem identification accomplished through a detailed assessment of the individual's needs, interests, activity level, health status, functional ability, and readiness to change. This assessment of individual health, lifestyle behaviors, and function, in conjunction with an evaluation of the individual's family support, community resources, and environmental barriers, allows a personalized physical activity program to be tailored for the individual. Jointly, individual-, family-, and community-level *strengths* and *resources* are harnessed to help the individual overcome barriers to physical activity.

While implementation of the resulting PEP intervention in the context of long-term support is expected to result in

increased physical activity and improved health outcomes, more research needs to be conducted to determine the effectiveness of this model (21,22). Establishment and maintenance of social support networks are an important component of maintaining physical activity behaviors in people with disabilities. The individualized assessment, in conjunction with an evaluation of community resources (e.g., community swim programs, accessible fitness centers), allows for a personalized physical activity program that is based on customized information. Both individual and community-level *strengths* and *resources* are utilized to help the patient/client overcome barriers to participating in a sport or other type of physical activity at home or in the community. Establishment and maintenance of social support networks that include building community friendships with other people, in addition to parental and/or caregiver support, are important components for maintaining participation over an extended period until health benefits are achieved (21,22). These networks may include personal contacts with family members or caregivers or may involve friendships formed through exercise classes or nutritional cooking classes offered as part of a community-based program.

The dynamic design of the PEP intervention model and its *person-centered* approach allow the rehabilitation professional to revise and modify the program at any time until the recommendations are *calibrated* or *recalibrated* (as in the case with an illness or new secondary health condition) to the user's needs and interest level. In Figure 54-2, the first step of the PEP intervention model is illustrated in the left column, *comprehensive needs assessment*, which includes the following components: (a) physical activity profile and activity preferences, (b) barriers to participation, (c) health status and mobility limitations, and (d) motivational level (readiness to change). Each of these components is described below.

### Components of the PEP Intervention Model

#### Physical Activity Profile

Understanding the patients/clients' physical activity participation history in sports, recreation, and/or fitness before (when possible) and after the onset of a disability is critical to

**FIGURE 54-2.** PEP intervention model.

designing an effective program. An assessment of a patient/client's specific disability and functional level, along with personal activity preferences, can help determine potential activities. For example, if a person with a spinal cord injury was an enthusiastic softball or basketball player before his or her disability, finding links to participating in wheelchair softball or basketball, whenever possible, may be more appealing and increase the individual's participation. As discussed in the second section, any recreation, fitness, and sport activity can be adapted for a person with a disability that should motivate rehabilitation professionals to learn more about how this can be accomplished for certain clientele.

### Barriers to Physical Activity

Personal and environmental barriers can impose substantial limitations in maintaining a physically active lifestyle. Among people with disabilities, some of the more common barriers are pain, lack of transportation, insufficient financial resources to pay for a health club membership, lack of awareness of community-based programs, and not knowing how to perform certain types of exercises or recreational activities. Usually, more specification is required in developing exercise programs for disabled populations because certain impairments and activity

limitations can limit an individual's access to a program or activity. As certain barriers are identified and removed, participation in various types of physical activities will likely increase.

One of the major concerns associated with increasing physical activity participation among people with disabilities is the lack of access to many community sports, recreation, and fitness programs (23). People with disabilities encounter enormous barriers in the built and natural environment (6). Indoor and outdoor structures have a major effect on participation in physical activity among people with disabilities (24,25). Structures such as gyms, fitness centers, outdoor trails, parks, and swimming pools often have poor signage, lack detail on how to use the equipment or participate in a program, or provide poor access routes to and from the facility or program.

Indoor environments of many fitness and recreation facilities also need to become more accessible for people with disabilities. One of the major barriers is inaccessible exercise equipment (26). Most manufacturers do not consider in their design specifications how to make their equipment accessible for people with physical, cognitive, and sensory disabilities. Typically, commercial cardiovascular exercise equipment requires propulsion by using the musculature of both lower extremities (i.e., treadmills, stationary bikes,

elliptical cross-trainers, and steppers), thereby restricting use among people with lower-extremity disabilities (e.g., paralysis, limb loss). While a few fitness facilities may be able to purchase a commercial quality arm cycle or wheelchair ergometer, the vast majority of fitness centers either cannot afford this equipment or do not find it cost-effective to purchase one for a small percentage of their clientele. Another problem with inaccessible equipment is that offering clients with disabilities the opportunity to use one piece of adaptive exercise equipment while the rest of the membership has access to all of the equipment clearly limits the amount of enjoyment and benefit that can be obtained from a more diversified program.

People with visual or cognitive disabilities also have difficulty using various types of exercise equipment (27). Display panels are often difficult to read or understand, getting on and off the equipment presents some risk of falling, and machines are often hard to propel or lift (e.g., weights are too heavy to lift) for people with low strength levels.

Programmatic issues are also barriers for people with disabilities (28). Fitness and recreation classes such as aerobic dance, yoga, and tai chi are often taught by instructors who have minimal knowledge of how to adapt their program for someone with a disability. Spoken directions regarding the types of exercises or movements the class is being asked to perform tend to be terse or vague. Rehabilitation specialists must have a good understanding of how to overcome certain barriers in order to ensure that the patient/client can successfully participate in various types of community-based programs.

### Health Status and Mobility Limitations

A rehabilitation professional must also understand the health and mobility limitations that prevent a patient/client from engaging in certain types of physical activities. Various types of disabilities include impairments such as loss of balance, vision, hearing, pain, fatigue, decreased cognition, paralysis, and many others. Each of these impairments can have an effect on the physical activity recommendations. Similarly, mobility limitations such as difficulty walking, climbing steps, transferring from a wheelchair, etc., must all be considered when designing a physical activity program that will match the individual's functional level.

### Motivational Level

Finally, for successful participation in any form of physical activity, the rehabilitation professional must find innovative ways to encourage participants to obtain regular physical activity. People with disabilities are often demotivated because of a number of barriers preventing them from becoming physically active (6). The stages of change model (29,30) includes five stages: precontemplation—no intention to change a behavior in the foreseeable future; contemplation—awareness that he needs more physical activity but has not yet made a commitment to take action; preparation—intending to take action in the next month but has unsuccessfully taken action in the past year; action—interested in modifying behavior to increase physical activity; and maintenance—individual is engaging in

physical activity. The stage of change that a patient/client is experiencing is often dependent on personal and environmental barriers. Therefore, assistance in identifying and addressing these barriers, helping the individual to appreciate the benefits of regular physical activity, as well as greater access to various forms of physical activity can help improve physical activity participation.

### Community-Based Physical Activity Options

The need to continue the recovery process after an injury or disability must include access to various types of physical activities in the person's community (31,32). In order to avoid boredom or lack of interest in a specific physical activity program, it is optimal to offer as many activity options as possible. Certain individuals may prefer group exercise (i.e., an aqua-aerobics class) in a community-based setting, while others may choose to exercise alone in their home or engage in some form of outdoor activity. Regardless of preference, a variety of options should be available. In the second section, such community-based physical activity options and resources are reviewed.

### Types of Physical Activities

The pyramid in Figure 54-3 illustrates different types of physical activities that can be engaged in over the course of the day. With rising obesity rates and low levels of energy-requiring activities at work and home, it is critical that all forms of physical activity be increased over a 24-hour period. Even simple movements (i.e., moving between commercials) can result in substantial accumulations of energy expenditure over the course of the day.

At the base of the pyramid is *residual activity*. This type of activity is generally performed at a very low intensity threshold and involves frequent unstructured movements, such as getting up and down from a chair, walking into different areas of the home, fidgeting, moving arms, etc. While residual activity does not offer any formal mechanism for structuring physical activity, the more an individual moves during the day, the higher the energy expenditure. Any activity above sitting, lying down, or sleeping requires greater energy expenditure and therefore higher calorie output.

FIGURE 54-3. Physical activity pyramid.

The next level of the pyramid is *task-oriented physical activity*. These types of activities relate to certain indoor and outdoor household tasks such as cleaning, doing laundry, shopping, driving a car, doing yardwork, etc. Several of these activities can be strenuous in nature and provide effective ways to increase energy expenditure in individuals who generally have low levels of physical activity or are somewhat deconditioned and/or uninterested in engaging in structured activities. The third level of the pyramid is *leisure physical activity*, which includes structured and planned physical activities such as leisure walking, bike riding, hand cycling, outdoor yard games, bowling, team and individual sports, fishing, etc. This form of physical activity can range from very low to moderate intensity activity. At the top of the pyramid is *fitness-related activity*, which is the most strenuous type of activity, with the highest rate of return in terms of improving health and function.

Rehabilitation professionals can assist their patients/clients to incorporate each level of physical activity within their daily regimen so that daily energy expenditure is increased. For example, residual activity can be performed at regular intervals during the day (i.e., get up or push wheelchair to another room between commercials, spend 5 minutes at the end of every hour moving arms or legs); to increase task-oriented physical activity, more chores can be completed inside and outside the home (i.e., dusting, cleaning windows, mopping or sweeping floor, cleaning appliances, grocery shopping, etc.); leisure physical activity can include new hobbies, such as tennis or bowling, leisurely walks or rolls for a few minutes several times a day, joining a chair exercise class, etc. Fitness-related activities can generally be performed for less than 1 hour, compared to the other forms of physical activity that are demonstrated at lower intensity thresholds. The next section provides many different recommendations for increasing two types of physical activities, leisure/sports, and fitness-related activity.

## RESOURCES IN PHYSICAL ACTIVITY AND DISABILITY FOR REHABILITATION PROFESSIONALS

One of the most important elements of this chapter is to provide rehabilitation and health professionals with a one-stop resource for identifying physical activity materials that can be used to facilitate/promote/prescribe participation among people with various types of physical, cognitive, and sensory disabilities. While textbooks provide a framework for guiding professionals in planning and developing rehabilitation programs, when it comes to physical activity, the Internet is extremely important for identifying key resources that can be passed on to the patient/client including specific information related to his or her disability and engaging in various types of physical activities, resources on how to exercise or use an exercise facility, and, most importantly, video clips demonstrating various types of exercises or physical activities that are easier to visualize than explain. The National Center on Physical and Disability has been funded since 1999 to promote physical

activity among people with disabilities. This resource center will allow clinicians to identify materials, programs, etc., for their patients/clients.

### The National Center on Physical Activity and Disability

As has been discussed in the first section, participation in fitness, recreation, and sport is more likely to succeed if programming is tailored to the participant's abilities and interest levels, while simultaneously addressing the barriers that these individuals may encounter for participating in such activities. The National Center on Physical Activity and Disability (NCPAD, [www.ncpad.org](http://www.ncpad.org)) addresses these problems by making sports and physical activity programs more accessible to people with disabilities through advanced Internet technologies that can assist rehabilitation professionals to develop appropriate, accessible physical activity programming (Fig. 54-4).

NCPAD serves as a central repository of information on physical activity and disability, actively collecting information from research, best professional practices, information on public and private recreation and fitness facilities serving people with disabilities, and businesses that provide equipment and services supporting physical activity participation by people with disabilities. In addition, NCPAD has actively promoted the importance of physical activity in attaining and maintaining optimal health for people with disabilities. This is being accomplished through a variety of promotional resources and outreach activities in partnership with advocacy organizations, service providers, and individual consumers.

Rehabilitation professionals can use the NCPAD web-based resources when designing treatment programs for patients/clients that include acute care guidelines, in addition to web-based physical activity assessment tools, and information on community-based resources and activity programs that promote long-term physical activity maintenance.

NCPAD's information is centralized on its Web site ([www.ncpad.org](http://www.ncpad.org)), which provides a range of resources on physical activity and disability: information on physical activity and disability, networking opportunities, searchable databases, assessment tools, and research. NCPAD Information

FIGURE 54-4. National Center on Physical Activity and Disability.

Specialists are available at 800-900-8086 or [ncpad@uic.edu](mailto:ncpad@uic.edu) to answer questions, including but not limited to appropriate exercise for individuals with a specific disability, available adaptive equipment, the location of accessible fitness programs and sport team opportunities, and more.

### Information on Physical Activity and Disability

Factsheet topics include physical activity (i.e., lifetime sports, competitive sports, exercise/fitness, and leisure), disability/health conditions, nutrition, and wellness. Factsheets on specific disabilities, for example, encompass an overview of the disability; aerobic, strength, and flexibility components for developing an appropriate fitness program; precautions and safety guidelines for exercising with a specific disability; and key organization contacts and references by local community. Sports and recreation factsheets provide general information about the benefits of the activity, rules and regulations, and key contact organizations. Many factsheets have embedded video clips so that the specific sport or exercise technique can be demonstrated to the user (<http://www.ncpad.org/videos/>), and some are available as videos/DVDs/quick series booklets that can be purchased at NCPAD's web shop (<http://www.ncpad.org/shop/>). NCPAD's free monthly newsletter (<http://www.ncpad.org/newsletter/newsletter.php?letter=current>) also provides updates on new NCPAD resources, fitness trends for people with disabilities, secondary condition prevention, as well as information on events and conferences, grants, and employment information.

### Searchable Databases

NCPAD's online searchable databases can assist professionals in locating appropriate physical activity programs and organizations, adaptive equipment and devices, and qualified personal trainers. These resources can help rehabilitation professionals involve their patients/clients in community-based physical activities and sports and/or obtain physical activity support and training from fitness professionals.

A web-based directory of accessible physical activity programs (including sports, recreational, and exercise/fitness activities) for people with disabilities and chronic health conditions (<http://www.ncpad.org/programs/>) and organizations providing health promotion and community-based resources for people with disabilities (<http://www.ncpad.org/organizations/>) may be searched by geographic area or topic. A suppliers database (<http://www.ncpad.org/suppliers/>) contains information on equipment and assistive devices for sports and recreation for people with disabilities, and a personal trainers database (<http://www.ncpad.org/trainers/index.php>), also searchable by geographic area, supplies information about personal trainers who have experience working with people with disabilities and chronic health conditions.

### Networking Opportunities

Web-based forums in the areas of networking (exercise professionals, exercise buddies), adaptive equipment, community resources (services, funding, programs), research (grants, articles), adherence ideas/suggestions, and best practices on accessibility (<http://www.ncpad.org/>) can help rehabilitation professionals

exchange information, above and beyond that available through the NCPAD Web site and the Information Specialists. The "Your Writes" section (<http://www.ncpad.org/yourwrites/>) also provides articles and information written by people with disabilities, family members, and caregivers on health promotion opportunities and resources for people with disabilities.

### Assessment Tools and Research

NCPAD and its related projects include assessment instruments and resources on evaluating physical activity levels and accessibility for people with disabilities to participate in fitness and recreation programs and facilities. Additionally, resources are available to assist professionals who are developing evidence-based programs, applying for grants, or designing a research study.

Evaluation tools include the PADS (Physical Activity Disability Survey) and B-PADS (Barriers to Physical Activity and Disability Survey) instruments. The PADS is designed to assess low-level physical activity among persons with physical disabilities and chronic health conditions (<http://www.ncpad.org/>) and the B-PADS, barriers to physical activity encountered by persons with disabilities, specifically personal (e.g., lack of motivation, fear of leaving home, perception of exercise as difficult or boring) and environmental barriers (e.g., lack of transportation, costs, and availability of fitness and recreation facilities). Assessment tools can also help to regularly measure steps logged per day, as well as body mass index and weight.

NCPAD's AIMFREE (*Accessibility Instruments Measuring Fitness and Recreation Environments*) manuals are a validated series of questionnaire measures that can be used by persons with mobility limitations and professionals (i.e., fitness and recreation center staff, rehabilitation professionals, owners/managers of fitness centers) to assess the accessibility of recreation and fitness facilities, including fitness centers and swimming pools. The instruments are available for purchase at NCPAD's web shop (<http://www.ncpad.org/shop/>).

For rehabilitation professionals interested in research, the Web site references section provides listings of books, journals, newsletters, videos, pamphlets, reports, theses, and proceedings (<http://www.ncpad.org/refs/books/>). Abstracts of current research articles on physical activity and disability are available at <http://www.ncpad.org/research/> and presentations on physical activity and disability at <http://www.ncpad.org/presentations/>. The monthly NCPAD newsletter also contains up-to-date information on grants and events/conferences (<http://www.ncpad.org/newsletter/newsletter.php?letter=current>) and includes information on new or interesting recreation, leisure, and sports programs offered to people with disabilities throughout the country.

### Fitness Programming for People with Disabilities

Physical fitness is an important area of emphasis in improving health among people with disabilities. The three primary components of fitness include cardiorespiratory endurance, muscular strength and endurance, and flexibility.

Cardiorespiratory endurance or aerobic capacity refers to the ability of the heart (cardio) and lungs (respiratory) to provide sufficient blood flow to working muscles for sustained

physical activity. Muscular endurance is defined as the muscle's ability to exert force for a sustained period of time, and muscular strength refers to the ability to generate force one time. Both contribute to improved balance, mobility, and stability, as well as improvements in BADL and IADL. Flexibility is the movement capability (i.e., range of motion) of muscle groups around a joint and can help to reduce injury, improve posture, and perform ADL and IADL (33,34).

Below are a series of guidelines for developing fitness center programming for people with disabilities with respect to cardiorespiratory endurance, strength, and flexibility (Table 54-1). The NCPAD ([www.ncpad.org](http://www.ncpad.org)) resources can be used for finding a fitness center in a specific geographic area, as well as locating adapted equipment. Note that these considerations do not generally apply to leisure and competitive sports and activities, which are less likely to be closely monitored for safety and specific conditioning effects.

Before beginning an exercise program, a patient/client's physician should be informed so that adequate precautions can be taken, and possible side effects of medications considered (Table 54-2). The American College of Sports Medicine (ACSM) (35) recommends that individuals with certain risk factors for exercise have a graded exercise test to determine how the heart responds to stress and whether there is adequate blood flow to the heart during increasing levels of activity. See the NCPAD factsheet on "Exercise Guidelines for People with Disabilities" ([http://www.ncpad.org/exercise/fact\\_sheet.php?sheet=15&view=all](http://www.ncpad.org/exercise/fact_sheet.php?sheet=15&view=all)) for more information.

In order to locate an exercise professional who has adequate education and experience, seek out recommendations from health professionals or national disability organizations. Though there are no national standards or educational requirements necessary to be an exercise professional, the ACSM, the American Council on Exercise (ACE), and the National Strength and Conditioning Association (NSCA) all issue certifications recognized nationally by exercise professionals. Moreover, some organizations assist with finding a certified professional in an area, including NCPAD's personal trainer database (<http://www.ncpad.org/trainers/index.php>) and the ACSM ProFinder.

**TABLE 54.1** Considerations Prior to Involvement in Fitness Training

- Inform physician of intentions to engage in physical activity if you are uncertain the patient/client is safe to participate in higher intensity levels of exercise.
- Determine side effects of medication on exercise.
- Consult a trained exercise professional to design an exercise prescription or identify resources for exercise programming for people with disabilities through the ACSM Web site ([www.acsm.org](http://www.acsm.org)).
- A graded exercise test may be warranted for some patients/clients if there is any concern about safely performing moderate- to vigorous-intensity exercise.

**TABLE 54.2** Parameters for Choosing an Exercise Professional and Fitness Center

- Education and experience
- Personal preferences
- Training frequency
- Location
- Cost
- Social skills

Other important considerations include the personality and gender of the professional, training frequency, the availability of the professional, whether training is desired at home or in a gym, and cost. For more tips, see the NCPAD factsheet "How to Choose a Personal Trainer" ([http://www.ncpad.org/fitt/fact\\_sheet.php?sheet=384](http://www.ncpad.org/fitt/fact_sheet.php?sheet=384)).

In choosing a fitness center, similar considerations apply. Depending on the patient/client's disability and functional level, accessibility of both the center and the equipment is critical. Exercise equipment using universal equipment design is preferable, as it is accessible for persons with and without disabilities. Moreover, other factors such as availability of staff on site, location, transportation options, and cost should also be considered. See transformation in a "Before-After Fitness Center Makeover" (<http://www.ncpad.org/get/fitnessCenter/index.html>), and view a virtual accessible community fitness center at <http://www.ncpad.org/get/VirtualTour/Welcome.html>. The NCPAD's programs database (<http://www.ncpad.org/programs/>) can help to locate fitness centers by geographic location and other search parameters.

Various indicators of exertion should be monitored during fitness programming so that the individual stays within an optimal and safe cardiovascular workout zone (Table 54-3). Rating of perceived exertion (RPE) should be monitored by

**TABLE 54.3** Cardiorespiratory Fitness Suggestions

- An exercise prescription for individuals with neurologic conditions should include the same four elements that are used with the general population: frequency, intensity, duration, and type. Check the ACSM Web site ([www.acsm.org](http://www.acsm.org)) for resources on developing exercise prescription guidelines.
- Any activity that increases energy expenditure above rest safely and effectively can be used to improve cardiorespiratory fitness.
- Patients taking  $\beta$ -blockers and those with autonomic dysfunction can have a blunted heart rate response. In these instances, consider using the RPE scale.
- Monitor RPE, heart rate, and blood pressure during early stages of activity and new programs.
- Teach proper breathing techniques (i.e., deeper vs. shallow breaths and "think tall" to maintain good posture) to avoid dyspnea (breathlessness).
- Vary workout to maintain interest.

**TABLE 54.4 Sample Cardiovascular Exercise Equipment for People with Disabilities Who Are Unable to Use Their Legs to Exercise**

- Upper arm ergometer
- Wheelchair ergometer
- Nu Step recumbent stepper
- BioStep Semi-Recumbent Elliptical
- Schwinn Airdyne (i.e., arm device only)
- VitaGlide

using the Borg RPE scale, which measures intensity of exercise on a scale from 6 to 20, or the conversation rule, in which one is able to converse while exercising. Heart rate must be gauged by finding the pulse and comparing this to the target heart rate.

In some cases, blood pressure should also be checked by an exercise professional during exercise or sport. For some individuals with physical disabilities, hypertension (i.e., stroke) or hypotension (i.e., spinal cord injury) is a common health condition. Once the individual adjusts to the program without wide fluctuations in blood pressure, it can be measured before and after activity.

Though a wide range of activities and sports are available to obtain a cardiovascular workout, including walking, wheelchair rolling, cycling, and swimming, as well as recreational and competitive sports (see <http://www.ncpad.org/lifetime/> for more suggestions), specific types of cardiovascular exercise equipment can assist wheelchair users and individuals with lower-extremity impairments in obtaining a cardiovascular workout (Table 54-4).

An ergometer is an upper and/or lower body–driven exercise device that is powered from a stationary position and allows for a cardiovascular workout. The common stationary exercise bike is one type, though other variations exist for individuals with physical disabilities. Most ergometers use some form of hand or foot pedal for the basic motion, and some models allow for wheelchair access. See the NCPAD “Ergometers and Exercise Cycles” factsheet ([http://www.ncpad.org/exercise/fact\\_sheet.php?sheet=5&view=all](http://www.ncpad.org/exercise/fact_sheet.php?sheet=5&view=all)) for more information.

Ergometers come in upper-, lower-, and dual-extremity models. For example, the Saratoga Cycle can be used from a table top for an upper-body workout and/or placed on the floor for lower-body exercise through pedaling (Fig. 54-5). Hand grips or foot straps can assist with full, partial, or nonexistent hand or foot grip. Motorized movement trainers, such as the MotoMed Viva, allow for passive, active, and active-assist exercise for a lower-extremity workout for individuals with limited function. Wheelchair ergometers allow for upper- and lower-body workouts through a wheelchair being mounted on a support with the driving wheels mounted on an elongated central shaft.

Other types of ergometers and exercise cycles that can be powered by upper, lower, and dual extremities include the Nu

**FIGURE 54-5.** A Saratoga Cycle® can be positioned on a table top for an upper-body workout or placed on the floor for lower-body exercise through pedaling. Courtesy of the Rehabilitation Institute of Chicago and the National Center on Physical Activity and Disability ([www.ncpad.org](http://www.ncpad.org)).

Step recumbent stepper and the Schwinn Airdyne exercise bike (Fig. 54-6). The Nu Step recumbent stepper includes a reclining back rest and a swivel seat, which simultaneously exercises arms and legs in a smooth, full range motion. Design features allow for either the lower and/or upper body to power the stepper, depending on the individual's disability and strength capacity. The Schwinn Airdyne exercise bike is also designed with a progressive resistance pedal system, which can be used jointly or separately by the upper or lower body.

A variety of guidelines should be followed to help ensure the safety and effectiveness of a physical activity program or sport (Table 54-5). Most importantly, the patient/client must

**FIGURE 54-6.** Nu Step recumbent stepper, with a reclining back rest and a swivel seat, allows for an upper- and/or lower-body workout. Courtesy of the Rehabilitation Institute of Chicago and the National Center on Physical Activity and Disability ([www.ncpad.org](http://www.ncpad.org)).

TABLE 54.5	Safety Guidelines and Reducing Injury
Reducing injury in people with disabilities	
<ul style="list-style-type: none"><li>• Stop exercise if pain, discomfort, nausea, dizziness, light-headedness, chest pain, irregular heartbeat, shortness of breath, or clammy hands are experienced.</li><li>• Adequate fluid intake is necessary.</li><li>• Appropriate clothing can help to avoid overheating.</li><li>• Realistic short-term and long-term goals must be established.</li><li>• The exercise program must meet the patient/client's goals.</li><li>• Overuse injuries can be avoided by varying exercise routine (e.g., cross-training) and using proper equipment.</li><li>• Pain and fatigue levels must be monitored closely.</li><li>• Balance must be assessed prior to engaging in standing activities (e.g., weight routine, aerobic dance class).</li></ul>	
Reducing injury in wheelchair users	
<ul style="list-style-type: none"><li>• Workout gloves with adequate padding can help avoid hand injury.</li><li>• Push rims should be padded.</li><li>• The angle of push rims to the seat must be optimally positioned to provide the most comfortable and efficient push angle.</li><li>• Legs should be securely strapped.</li><li>• Adequate stretching is necessary prior to the workout.</li></ul>	

be aware of how his or her body is responding to the activity, so that appropriate adjustments can be made. Ideally, an exercise program should be varied, which can help to avoid overuse injuries. Balance should also be assessed to determine readiness for standing activities.

For wheelchair users, adequate precautions must be taken to avoid overuse injury, as well as additional injuries, due to the activity. Stretching is necessary to prepare individuals with spasticity for the workout, and using workout gloves and push rim padding can help to protect hands.

Strength training prescriptions for people with disabilities are based largely on disability severity, functional muscle mass, and health status (Table 54-6). Some patients/clients can train at very high intensity levels, while others will only be able to perform at minimal levels of resistance (i.e., lifting a body part against gravity). The training load (number of sets and repetitions, frequency, rest interval between sets) also varies by disability type, health status, and functional muscle mass. With respect to disability type, individuals who do not have a progressive disorder (i.e., spinal cord injury, cerebral palsy) can work at higher intensity levels than persons with progressive disorders (i.e., multiple sclerosis, postpolio).

An individual's health status also affects how quickly a person is able to progress during the conditioning stage. Many individuals with physical disabilities who have been inactive for much of their lives need only a small amount of resistance exercise during the initial stage of the program to obtain a training effect. For example, a person with stroke and hypertension should not perform high intensity exercise. Individuals who are seizure prone or fatigue easily require a reduction in training volume.

TABLE 54.6	Strength Training Guidelines
<ul style="list-style-type: none"><li>• Strength training prescription and training load are determined by disability severity, functional muscle mass, and health status.</li><li>• Resistance goals must be clarified to determine strength training schedule.</li><li>• Proper breathing techniques and a complete range of motion must be followed.</li><li>• Blood pressure should be monitored during strength training.</li><li>• Adaptations may be necessary for individuals with hand dysfunction and asymmetrical weakness.</li><li>• Focus on stability, coordination, ROM, and timing.</li><li>• Wide benches, low seats, and trunk and pelvic strapping will help support and protect the person from injury during the exercise routine.</li><li>• Avoid "hiking" the body on the weak side.</li><li>• Avoid person holding breath while lifting weight (i.e., Valsalva maneuver).</li><li>• Use straps whenever necessary to keep body part in contact or alignment while lifting weight.</li></ul>	

The amount of functional muscle mass also affects training volume. Persons with paralysis, hemiplegia, impaired motor control, or limited joint mobility have less functional muscle mass and will therefore require a lower training volume. For individuals who cannot lift the minimal weight on certain resistance machines, resistance bands or cuff weights or even the person's own body weight can be used as the resistance.

Modes of resistance exercise consist of three general categories: free weights, portable equipment (i.e., elastic bands, tubing), and machines. While free weights may be preferable because they resemble functional daily activity (36), they require good trunk stability and may be difficult to perform for individuals with severe limitations in motor control and coordination. For individuals with very low strength levels, gravity-resistance exercise may be all that the person is capable of doing, and active-assistive exercise may be required for certain muscle groups that are too weak (paresis) or tight (spasticity) to be moved independently.

Precautions for assisting persons with disabilities with strength training include avoiding fatigue and exacerbations, assisting with asymmetrical weakness and hand dysfunction, and checking blood pressure routinely. Fatigue and delayed-onset muscle soreness in individuals with physical disabilities should be avoided, though this is common in new resistance training programs. Exercise should be stopped temporarily if soreness in certain muscle groups prevents the person from performing routine daily activities, and a physician should be contacted if fatigue persists. Similarly, individuals with asymmetrical weakness tend to hike their body disproportionately in resistance training and must be encouraged to use proper form.

For individuals with hand dysfunction who have difficulty grasping barbells or handles on different strength machines, a variety of specially-designed gloves allow the person's hand to

maintain contact with the resistance equipment. Gloves will also protect the hand from injury while performing resistance training routines. Individuals who do not have good grip strength can use wrist cuffs or leather mitts with velcro and buckles to secure their hands to dumbbells or weight equipment (Fig. 54-7). Blood pressure should also be monitored frequently during the early stages of the program, and as for some disabilities, hypertension or hypotension can be a common problem.

Finally, safe and effective strength training must include proper breathing techniques and extend through a complete range of motion. Breath should not be held during strength training, but the patient/client must exhale or breathe out while pushing the weight up or out and inhale or breathe in while letting the weight down or in. Proper posture facilitates effective breathing techniques.

Flexibility exercises help to improve range of motion, balance, and coordination, as well as the ability to carry out regular activities of daily living (Table 54-7). They can be performed every day and should be conducted before and after every cardiovascular and strength workout.

A stretching program should last at least 10 minutes and should not be painful. Every muscle group used in a workout should be thoroughly stretched in a slow and fluid manner. They should be held and progress slowly, and more time should be spent on tight muscle groups. Types of flexibility training that can be easily adapted for people with disabilities include yoga and pilates.

Since many individuals with physical disabilities will have some degree of spasticity (tightness), flexibility training should always be combined with resistance training. An exercise professional must identify the “spastic” muscle groups and develop

**FIGURE 54-7.** Activity mitts or gloves can assist a person with hand dysfunction to grip equipment handles. Courtesy of the Rehabilitation Institute of Chicago and the National Center on Physical Activity and Disability ([www.ncpad.org](http://www.ncpad.org)).

**TABLE 54.7 Flexibility Guidelines for People with Disabilities**

- Flexibility training should be incorporated before and after each cardiovascular and strength workout.
- Stretches should be held and progress slowly.
- Each major muscle group should be thoroughly stretched.
- Special precautions should be taken to avoid spasticity.

a long-range plan to increase range of motion. If the joint has been in a “fixed” position for many years, or if the spasticity is severe, it may not be possible to fully extend the joint. An exercise professional should consult with a physical therapist, physician, or appropriate medical professional to determine how to stretch a spastic muscle without causing injury. As with resistance training, use active-assistive stretching for certain muscle groups that are too weak (paresis) or tight (spasticity) to be moved independently.

### Involvement of People with Disabilities in Leisure and Recreational Physical Activities

As has been discussed with respect to the physical activity pyramid, rehabilitation professionals can motivate and assist patients/clients to incorporate a range of activities within their daily schedule, including residual, task-oriented, leisure, and fitness-related physical activities (see Fig. 54-3). In this section, types of leisure and recreational activities adapted for people with disabilities are reviewed, along with resources that the professional can use in connecting the patient/client with community programs and resources. Table 54-8 identifies activities falling into leisure and competitive categories along the physical activity continuum. While team sports are more likely to be competitive in nature, both individual and team sports can be competitive or enjoyed for recreational purposes.

### Leisure Physical Activity

Many types of leisure physical activities are now available to people with disabilities (Table 54-8). The importance of leisure physical activity is not necessarily to improve fitness, although with many activities, fitness benefits can be attained, especially in deconditioned individuals: the important element is that the person is participating in an enjoyable activity that raises energy expenditure above resting levels and reduces sedentary behavior. The other nice feature of leisure physical activity is that many of the activities can be done for longer than 30 minutes and sometimes up to a few hours. Examples of beneficial leisure activities include gardening, dog walking/wheelchair rolling, bowling, dancing, and recreational swimming, kayaking, and sailing.

### Gardening

Gardening is considered an excellent leisure activity for increasing energy expenditure and for using various muscle groups that are not typically used in general activities. Bending, reaching, twisting, digging, etc., are all aspects of gardening that provide health benefits. Gardening can help improve balance, strength,

**TABLE 54.8 Sample Physical Activities for People with Disabilities**

and flexibility, depending on the types, intensity, and duration of activity (Fig. 54-8). Thus, one can adjust one's gardening for a heavier strength- and endurance-building workout or focus on less intensive activities using fine/gross motor skills, eye/hand coordination, as well as flexibility and balance.

A garden can be adapted for access in a variety of ways, starting with appropriate grades and paving, then careful selection and placement of planters, vertical gardening techniques such as hanging baskets, and, where possible, larger raised beds. These are all used to position soil and plants safely and comfortably within reach. A barrier-free or enabling garden can be as simple as an easily-reached window box hung from a balcony railing at waist height or an entire home landscape designed to be accessible and maintained by a wheelchair user.

Gardening tools and equipment also enable the individual to reduce effort, maximize abilities, and encourage independence while working in the garden. For example, long-handled tools decrease the need to extend or bend the body to work

**FIGURE 54-8.** One of 12 accessible hanging baskets in the Chicago Botanic Garden. Baskets can be lowered for watering and then raised. They operate on a geared crank to reduce the force needed to raise and lower the baskets. Photo by Eugene Rothert.

areas beyond the gardener's reach. Comfort and gripping ability can be improved by modifying handles with soft padding. Knee pads or kneelers can be useful for tasks close to the ground. Such tools help protect muscles and joints from fatigue and injury in order to find the best match for the garden tasks being done.

Resources: For additional information, refer to the gardening factsheets on the NCPAD Web site ([http://www.ncpad.org/fun/fact\\_sheet.php?sheet=301](http://www.ncpad.org/fun/fact_sheet.php?sheet=301); [http://www.ncpad.org/fun/fact\\_sheet.php?sheet=302](http://www.ncpad.org/fun/fact_sheet.php?sheet=302); [http://www.ncpad.org/fun/fact\\_sheet.php?sheet=306](http://www.ncpad.org/fun/fact_sheet.php?sheet=306)).

- Internet key words: Search terms, such as enabling garden, healing garden, accessible garden, horticultural therapy, and barrier-free gardening, etc., to identify links to many different resources related to gardening for people with disabilities.
- American Horticultural Therapy Association: <http://www.ahta.org> can help identify a nearby horticultural therapist who is adept at working with people with disabilities in gardens. The association also provides referrals to local health care agencies and public gardens with horticultural therapy programs, educational opportunities, and publications.
- Chicago Botanic Garden's Horticultural Therapy Services program: <http://www.chicagobotanic.org/therapy> provides demonstrations on enabling gardening, an extensive adaptive tool collection, publications, and educational programming.

## Bowling

Bowling is a popular recreational and competitive activity that can be enjoyed by individuals with disabilities through minimal equipment adaptations. Traditionally a sport in which players score points by rolling a bowling ball to knock down

**FIGURE 54-9.** Use of the bowling ball ramp for individuals who cannot carry or throw the bowling ball. Courtesy of the National Center on Physical Activity and Disability ([www.ncpad.org](http://www.ncpad.org)).

pins, both indoor and outdoor variations on the game can be employed. Benefits include improved flexibility and strength, as well as social engagement.

Adapted equipment is available for individuals of all ability levels to participate and compete in bowling. These include ball ramps, assisting those unable to throw a bowling ball; ball pushers or bowling sticks, which provide the participant with increased control over the force of the throw and the angle at which the ball travels down the lane; and aids for persons with visual impairments (Fig. 54-9).

Organized bowling opportunities for people with disabilities include groups associated with Special Olympics International (SOI), the United States Deaf Bowling Federation (USADBF), the National Disability Sports Alliance (NDSA), the American Wheelchair Bowling Association (AWBA), and the American Blind Bowling Association (ABBA).

Resources: For more information, see the NCPAD factsheet on bowling at [http://www.ncpad.org/lifetime/fact\\_sheet.php?sheet=16&view=all](http://www.ncpad.org/lifetime/fact_sheet.php?sheet=16&view=all).

## Dancing

Dance is a recreational or competitive activity for individuals with varying abilities. It involves creativity and expression while promoting movement, flexibility, and endurance. Dance

**FIGURE 54-10.** Diverse-ability dance troupe, “Dance Detour,” comprised of artists with and without disabilities. Courtesy of William Frederking, Dance Detour, Chicago, IL.

can decrease stress and increase muscle tone, physical endurance, and self-confidence. It may also increase brain activity and stimulate memory through the use of choreography and help prevent or lessen the effects of secondary conditions such as depression and social isolation.

The basic rules of wheelchair dance sport include the pairing of a male and a female partner, one of which must be a wheelchair user with at least a minimal disability that makes walking impossible (Fig. 54-10). Participants with disabilities in the lower parts of their bodies such as amputation, paralysis, cerebral palsy, and leg shortening (at least 7 cm) are eligible for competition. Participants are expected to have normal upper-body functions. There are two functional classes based on ability to maneuver a wheelchair, trunk rotation, and arm function. Competitive dance includes the waltz, tango, slow foxtrot, quickstep, samba, cha-cha-cha, rumba, and paso doble.

Social or recreational dance opportunities for people with disabilities can be located through accessible dance troupes and organizations. See resources below, and seek out similar opportunities locally. Classes may include ballet, hip hop, capoeira, modern dance, and jazz and can be adapted according to ability level.

Resources: For more information, see the NCPAD factsheet on dance at [http://www.ncpad.org/fun/fact\\_sheet.php?sheet=35&view=all](http://www.ncpad.org/fun/fact_sheet.php?sheet=35&view=all).

- Dancing Wheels: <http://www.dancingwheels.org>, T: 216-432-0306.

- Gallaudet Dance Company: <http://dance.gallaudet.edu/>, T: 202-540-8523.

### Swimming

Swimming is an excellent recreational, competitive, and therapeutic activity that can be enjoyed indoors or outdoors. In addition to swimming’s therapeutic role, other aquatic activities are popular for recreational purposes. The benefits of swimming and aquatic exercise include improved cardiovascular function, reduced stress on joints, and water resistance improving muscle strength. Additionally, an individual’s ability to swim and feel comfortable in the water create opportunities to become involved in other water sports including kayaking, canoeing, sailing, and water skiing.

For competitive swimming, a sport classification ensures that swimmers compete against others with similar functional abilities (Fig. 54-11). Swimmers with disabilities are encouraged to train under the supervision of a qualified coach who understands stroke mechanics and can recommend special stroke adaptations. USA Swimming teams (<http://www.usa-swimming.org>) are an excellent place to find a coach. Swimmers with disabilities can be easily integrated into existing clubs to obtain the necessary training and experience. With a few exceptions, swimmers are expected to perform strokes according to the rules of nondisabled swimming, and rulebooks are available from USA Swimming. The most elite swimmers compete in the Paralympic Games every four years.

Stair systems and pool lifts can be used for accessing pools, and all-terrain wheelchairs help to reach natural bodies

**FIGURE 54-11.** A competitive swimming match among individuals of different physical ability levels. Swimmers with disabilities are grouped by the S1–S15 sport classification system. Courtesy of the Rehabilitation Institute of Chicago and the National Center on Physical Activity and Disability ([www.ncpad.org](http://www.ncpad.org)).

of water. Though not permitted in sanctioned swim events, different prosthetic devices can reduce resistance in the water during the recovery portion of a swimming stroke. Similarly, flotation devices help stabilize individuals in the water.

**Resources:** For more information on swimming for persons with disabilities, see the NCPAD factsheets on swimming ([http://www.ncpad.org/fun/fact\\_sheet.php?sheet=17&view=all](http://www.ncpad.org/fun/fact_sheet.php?sheet=17&view=all)), swimming pool lifts ([http://www.ncpad.org/fun/fact\\_sheet.php?sheet=89&view=all](http://www.ncpad.org/fun/fact_sheet.php?sheet=89&view=all)), and swimming instruction for people with disabilities ([http://www.ncpad.org/fun/fact\\_sheet.php?sheet=90&view=all](http://www.ncpad.org/fun/fact_sheet.php?sheet=90&view=all)).

Swimming is an official sport of the United States of America Deaf Sports Federation (USADSF, <http://www.usdeafsports.org/>), the Dwarf Athletic Association of America (DAAA, <http://www.daaa.org>), the NDSA (<http://www.ndsaonline.org>), Wheelchair Sports USA (WSUSA, <http://www.wsusa.org/>), Disabled Sports USA (DSUSA, <http://www.dsusa.org/>), and the United States Association of Blind Athletes (USABA, <http://www.usaba.org/>).

Organizations especially pertinent for persons with disabilities interested in swimming include

- USA Swimming: <http://www.usa-swimming.org>, T: 719-866-4578
- WAUSA: <http://www.wsusa.org/>, T: 636-614-6784
- DSUSA: <http://www.dsusa.org/>, T: 301-217-0960

### Kayaking

Kayaking is a recreational activity in which individuals can experience the outdoors and obtain an excellent cardiovascular workout (Fig. 54-12). Kayaking can be practiced in many water-based locations and is easily adapted to various ability levels. The American Canoe Association (ACA) promotes the benefits of canoeing and kayaking while offering courses on the basics of paddling, safety and rescue courses, and instructor certification.

**FIGURE 54-12.** Individuals with prosthetics prepare to kayak and canoe.

Adaptations and modifications include paddles that can be adapted for individuals with amputations or hemiplegia due to a stroke or cerebral palsy. Grip adaptations can assist paddlers with visual impairments in learning the proper grip and hand placement on the paddle. Proper fit and comfort within the kayak are essential because water increases the breakdown of skin and can lead to an increased risk of pressure sores. Closed-cell foam and adaptive seating systems may be used for increased contact with the boat, as well as to create a backrest or seat cushion.

Types of kayaks include tandem, open-decked, whitewater boats, inflatables, and sea kayaks.

**Resources:** For more information, consult the NCPAD factsheet on kayaking at [http://www.ncpad.org/lifetime/fact\\_sheet.php?sheet=19&view=all](http://www.ncpad.org/lifetime/fact_sheet.php?sheet=19&view=all).

- Adaptive Adventures: <http://www.adaptiveadventures.org/>, T: 303-679-2770
- Paddlesports Industry Association: <http://www.paddlesport-industry.org/>, T: 800-789-2202

### Sailing

Sailing for people with disabilities can be practiced in both leisure and competitive contexts. It made its debut as a demonstration event in the 1996 Atlanta, GA, Paralympics, and became a full medal sport at the 2000 Sydney Paralympic Games. Using the International Association for Disabled Sailing (IFDS) Functional Classification System, Paralympic sailors with disabilities are classified according to their ability and can compete on a relatively equal basis.

With some adaptations, many standard boats are suitable for competition by people with disabilities. Types of adaptations include accessible and stable seats, transfer benches, and steering assists (Fig. 54-13). Seats and transfer benches can consist of low-tech furniture, such as lawn chairs or coolers, and specifically-designed equipment, such as a translating seat. Steering systems can also be adapted for the user. Bars and handles are secured throughout the boat for sailor stability and safety.

**FIGURE 54-13.** A wheelchair user is assisted onto a boat prior to sailing.

Local community organizations provide recreational sailing opportunities for people with disabilities. See the NCPAD's program database to search for a program in your area: <http://www.ncpad.org/programs/>.

- IFDS: <http://www.sailing.org/disabled>
- U.S. Sailing: <http://www.ussailing.org/swsn/links.asp,T:401-683-0800>

## Recreational Sports

Key recreational physical activities that can be adapted for people with disabilities include sports such as water and snow skiing, tennis, golf, and cycling and often more competitive team sports such as basketball, softball, volleyball, and quad rugby. While team sports are more likely to be competitive in nature, both individual and team sports can be competitive or enjoyed for recreational purposes.

In addition to elite Paralympic sports, the U.S. Paralympics also runs a series of nonelite programs, including those based in the community, an academy program for youth aged 12–18, and a military division for veterans wounded through combat. The goal of such programming is to involve people with disabilities from the community to develop healthy habits and a healthy self-concept through engagement in sport and competition. For more information, see the Paralympics web link: <http://www.usolympicteam.com/paralympics/>.

## Water Skiing

Water skiing is a recreational and competitive warm-weather activity that can be easily adapted for individuals with disabilities.

**FIGURE 54-14.** A man sitting in a ski cage, being fitted for a ski board. Courtesy of the Rehabilitation Institute of Chicago and the National Center on Physical Activity and Disability ([www.ncpad.org](http://www.ncpad.org)).

Benefits include the opportunity to develop aerobic and strength capacity, to learn new skills, and to compete.

Adaptive equipment allows skiers with disabilities to enjoy a variety of water skiing activities (Fig. 54-14). Skiers with arm and leg amputations generally use the same equipment as skiers without disabilities, but with adaptations. A ski harness assists skiers who have difficulty holding onto the towrope. A ski boom, used by beginner skiers, is a 15-foot bar that attaches onto the boat. Outriggers can be attached to the sit ski to help skiers who have difficulty with balance. Skiers with disabilities may also use a board (ski) that is similar to a surfboard with a seat (cage) attached to the top. The cage, typically made of padded metal tubes, is deep so that the skier can sit securely.

Competitive water skiing includes three events—slalom, trick skiing, and jumping—and six broad category divisions for the disability water skiing events. The sit skier division includes individuals with spinal cord injuries (paraplegia, quadriplegia), bilateral leg amputations, or other conditions that affect the lower limbs. The vision impairment division includes people with complete and partial vision impairment. The leg division is for skiers who have an above or below knee amputation, in which skiers can ski with or without their prosthesis (Fig. 54-15). The arm division includes skiers with either an arm amputation or an impairment of one arm, and the arm and leg division for skiers with an impairment of both upper and lower limbs.

Resources: For more information, access the NCPAD water skiing video clip ([http://www.ncpad.org/videos/fact\\_sheet.php?sheet=248&view=all](http://www.ncpad.org/videos/fact_sheet.php?sheet=248&view=all)).

- USA Water Ski: <http://www.usawaterski.org/>, T: 863-324-4341, a national governing body for water skiing, which works through the Water Skiers with Disabilities Association to serve individuals with disabilities.

**FIGURE 54-15.** A man skiing with prosthetic devices attached to the water ski. Courtesy of the Rehabilitation Institute of Chicago and the National Center on Physical Activity and Disability ([www.ncpad.org](http://www.ncpad.org)).

- U Can Ski 2: <http://ucanski2.com>, T: 863-967-2575, dedicated to providing public awareness and outreach opportunities for individuals with disabilities.

### Snow Skiing

Skiing is a competitive and recreational winter activity in which individuals use skis to maneuver downhill or cross-country. Benefits include improved cardiovascular conditioning, muscle core strength, balance, coordination, and flexibility. Skiing can be readily adapted for persons with disabilities and offers opportunity for competition or recreating with friends.

Adapted ski programs have grown due to the development of adaptive equipment for individuals with disabilities. Various organizations offer skiing events to encourage individuals of all abilities to participate. Information on adaptive equipment, teaching techniques, workshops, and certification clinics can be obtained from the Professional Ski Instructors of America (<http://www.psia.org>). Competitive alpine events include slalom, giant slalom, super giant slalom, and downhill. Cross-country events include men's 10K and 30K and women's 5K, 10K, and 4 × 10K relay races.

Skiing adaptations for people with disabilities include adapted skis and prosthetics, as well as adequate communication and instruction for the individual with

**FIGURE 54-16.** Use of the biski, with outriggers to maintain balance, and the instructor tethered to the skier. Courtesy of the Rehabilitation Institute of Chicago and the National Center on Physical Activity and Disability ([www.ncpad.org](http://www.ncpad.org)).

the disability. The monoski consists of a bucket-style seat attached to a single ski, with outriggers to maintain stability. A biski has a bucket-style seat attached to two skis and outriggers attached to the sled, three track skiing requires one ski and two hand held outriggers, and four track skiing requires two skis and two hand held outriggers (Fig. 54-16). Skiing for persons with visual impairments involves good communication between the visually impaired skier and a sighted guide providing the ski instructions. The U.S. Deaf Ski & Snowboard Association (<http://www.ussa.org/>), affiliated with USADSF (<http://www.usdeafsports.org/>), sponsors various championships, selects U.S. Deaf Ski and Snowboard Teams, and can provide information on skiing with a hearing impairment.

Resources: For more information, access the NCPAD skiing videoclip ([http://www.ncpad.org/videos/fact\\_sheet.php?sheet=247&view=all](http://www.ncpad.org/videos/fact_sheet.php?sheet=247&view=all)) or factsheet ([http://www.ncpad.org/lifetime/fact\\_sheet.php?sheet=33&view=all](http://www.ncpad.org/lifetime/fact_sheet.php?sheet=33&view=all)).

**FIGURE 54-17.** A wheelchair tennis player. Wheelchair tennis follows the two-bounce rule, where the wheelchair tennis player must return the ball before it hits the ground a third time. Courtesy of the Rehabilitation Institute of Chicago and the National Center on Physical Activity and Disability ([www.ncpad.org](http://www.ncpad.org)).

## Tennis

Tennis is a competitive recreational activity that has become increasingly popular among individuals with disabilities. Benefits include improved aerobic and anerobic fitness, gross and fine motor control, agility, balance, flexibility, hand-eye coordination, as well as bone strength and density. The sport is a cross-disability activity and can be played indoors or outdoors, in pairs or teams.

The two versions of tennis within disability sport include ambulatory tennis and wheelchair tennis. Ambulatory tennis is governed by two disability sport organizations, the United States Deaf Sports Federation and Special Olympics. Wheelchair tennis was developed in 1976 and is currently governed by the International Tennis Federation (ITF, <http://www.itftennis.com/>) and Wheelchair Tennis Committee, with advisement by the International Wheelchair Tennis Association (IWTA).

A wheelchair tennis match is played between two or four athletes with loss of motor function in one or both lower extremities (Fig. 54-17). Separate divisions exist for individuals by disability (quadriplegia or athletes with loss of motor function in the lower extremities and functional disability or amputation in the upper extremities), gender, skill level, and age. This allows for persons with disabilities to compete against able-bodied players.

To score a point, the ball must be hit in the opponent's court without the opponent returning the shot. The winner of the match is the athlete or pair to win three "sets" of six "games" each (best-of-three set match). Wheelchair tennis follows the same rules

as able-bodied tennis as endorsed by the ITF, with several key exceptions, the most significant of these being the "two-bounce rule," where the wheelchair tennis player is allowed two bounces before the ball must be returned across court. For more information about wheelchair tennis or an extensive list of rules, please refer to the ITF Wheelchair Tennis Handbook (<http://www.itftennis.com/wheelchair/rules/wheelchairtennishandbook.asp>).

Wheelchair tennis requires only a few pieces of equipment, a tennis racquet, ball, and a wheelchair, and is played on the same courts and surfaces as able-bodied tennis. No modifications are necessary for the racket and the ball. Players use a sports wheelchair that is lighter than everyday chairs to allow for ample flexibility, and the wheelchair is considered part of the player so that general rules of contact apply. To keep the player stable on the chair, a positioning strap across the waist and/or thighs is used. Grip devices are designed specifically for players who do not have the grip strength to hold a racquet. Arm and leg prosthetics are available for individuals who are amputees.

Resources: See the NCPAD wheelchair tennis video clip at [http://www.ncpad.org/videos/fact\\_sheet.php?sheet=44&view=all](http://www.ncpad.org/videos/fact_sheet.php?sheet=44&view=all).

## Golf

Golf is one of the most rapidly growing recreational activities in America, as it offers an opportunity for individual skill development, companionship, and socialization and can be played by persons of all abilities. Particularly for those who walk the course, golf provides for cardiovascular fitness, strength, and flexibility, as well as improved mental health.

Assistive devices for golfers with disabilities include specially-designed golf clubs, mobility devices, gripping aids, and practice facility equipment, including automated ball teeing devices, ball retrieval aids, etc. (Fig. 54-18). More information on golfing assistive devices can be found on the National Center on Accessibility (NCA) Web site at [www.ncaonline.org](http://www.ncaonline.org).

The U.S. Golf Association (USGA) maintains a "Modification of the Rules of Golf for Golfers with Disabilities" ([http://www.usga.org/playing/rules/golfers\\_with\\_disabilities.html](http://www.usga.org/playing/rules/golfers_with_disabilities.html)) for individuals wishing to play golf by these adjustments. Specific modifications are available for golfers with visual impairments, amputations, as well as those using canes, crutches, or wheelchairs.

Resources: The NCPAD golf factsheet ([http://www.ncpad.org/lifetime/fact\\_sheet.php?sheet=245&view=all#1](http://www.ncpad.org/lifetime/fact_sheet.php?sheet=245&view=all#1)) provides more information about the game, golf professionals, organizations, and equipment suppliers.

Courtesy of the Rehabilitation Institute of Chicago and the National Center on Physical Activity and Disability ([www.ncpad.org](http://www.ncpad.org)).

### Cycling

Cycling is a recreational and competitive activity that allows individuals to obtain a cardiovascular workout while strengthening corresponding muscle groups. Individuals can cycle with upper or lower extremities, in indoor or outdoor locations. It is an official sport of DSUSA, SOI, the USABA, the USADSF, and the NDSA. Competitive hand cycling is governed by the United States Handcycling Federation (USHF).

Each of these disabled sports organizations work cooperatively with USA Cycling to develop cycling opportunities throughout the United States. Events range from 400-m junior races offered by NDSA to 40-km road races offered by DSUSA and USABA. A wide variety of adapted cycles exist, including handbikes, arm-driven cycles, dual-recumbent cycles, and tandem cycles (Fig. 54-19). Ergometers and stationary cycles reviewed earlier in this chapter are also suitable for indoor activity for people with disabilities.

Resources: For additional information, read the NCPAD factsheet on cycling at [http://www.ncpad.org/competitive/fact\\_sheet.php?sheet=21&view=all](http://www.ncpad.org/competitive/fact_sheet.php?sheet=21&view=all).

- USHF: <http://www.ushf.org/>, T: 303-459-4159

**FIGURE 54-19.** A woman powers an arm-driven cycle towards the finish line.

### Basketball

Basketball is a team sport that can be played by individuals with a variety of disabilities. Though numerous variations exist, the two major versions of basketball popular within disability sport are ambulatory and wheelchair basketball. Benefits of playing basketball include the development of aerobic capacity and strength, as well as the opportunity to participate in different roles and positions on a team.

In wheelchair basketball, the wheelchair is considered part of the player, and therefore, general rules of contact apply (Fig. 54-20). The National Wheelchair Basketball Association (NWBA) has an extensive list of rules, and rule modifications exist from SOI, DAAA, and the NDSA. Basketball variations include bankshot basketball, which relies entirely on shooting skill and no running, dribbling, jumping, or body contact, and twin basketball, which is set up for athletes with cervical-level spinal cord injuries, with players surrounding a free throw circle.

Resources: For more information, access the NCPAD factsheet on basketball ([http://www.ncpad.org/competitive/fact\\_sheet.php?sheet=4&view=all](http://www.ncpad.org/competitive/fact_sheet.php?sheet=4&view=all)) and videoclip on wheelchair basketball ([http://www.ncpad.org/competitive/fact\\_sheet.php?sheet=4&view=all](http://www.ncpad.org/competitive/fact_sheet.php?sheet=4&view=all)).

- NWBA: <http://www.nwba.org/>, T: 719-266-4082
- NDSA: <http://www.ndsaonline.org/>, T: 401-792-7130
- USADSF: <http://www.usdeafsports.org/>, T: 605-367-5760
- International Wheelchair Basketball Federation: <http://www.iwbf.org/>, T: 204-632-6475

### Softball

The game of softball can be easily adapted for individuals with disabilities and played within competitive or recreational contexts. Benefits include participation in a team sport and social activity involving skill and strategy, as well as improved

**FIGURE 54-20.** A wheelchair basketball player illustrates throwing technique. Courtesy of U.S. Paralympics, the Rehabilitation Institute of Chicago, and the National Center on Physical Activity and Disability ([www.ncpad.org](http://www.ncpad.org)).

hand-eye coordination, strength and endurance, and mobility skills.

Variations on the game include wheelchair softball and beep baseball, and different softballs can be used for variations on the game. Batting and fielding equipment are available for individuals with upper-extremity amputations. Competition is offered by the USADSF (<http://www.usdeafsports.org/>), the DAAA (<http://www.daaa.org>), SOI (<http://www.specialolympics.org>), the National Wheelchair Softball Association (NWSA) (<http://www.wheelchairsoftball.org/>), and the National Beep Baseball Association (<http://www.nbba.org>).

Wheelchair softball requires that all players participate from a wheelchair, and all teams must have a team member with quadriplegia in play (Fig. 54-21). When on offense, the individual must be in the batting lineup, and on defense, the individual with quadriplegia must play the field. A team that chooses not to play a team member with quadriplegia must incur an automatic out every tenth batter. Each team must abide by the classification system that requires that no team can earn more than 22 points at any time during a game. If a player leaves his or her chair to gain a fielding advantage, all base runners advance two bases. For throwing errors in which the ball leaves the playing area, each base runner advances one base. Rule modifications (<http://www.wheelchairsoftball.org/rules.htm>) and general information are available from the NWSA (<http://www.wheelchairsoftball.org/>).

Beep baseball is an adaption on the game for individuals with visual impairment and blindness. The game consists of

**FIGURE 54-21.** A wheelchair softball player at bat. Courtesy of the Rehabilitation Institute of Chicago and the National Center on Physical Activity and Disability ([www.ncpad.org](http://www.ncpad.org)).

4-ft-high padded cylinders with speakers and a sighted pitcher and catcher. Beeping tones are emitted as the pitcher places the ball, and as the ball is hit, the base operator activates a buzzing sound for the batter to identify and run to the base prior to the defense fielding the ball. For more information, contact the National Beep Baseball Association (<http://www.nbba.org>).

Resources: Access the NCPAD factsheet on softball ([http://www.ncpad.org/competitive/fact\\_sheet.php?sheet=32&view=all](http://www.ncpad.org/competitive/fact_sheet.php?sheet=32&view=all)) for more information on the game.

## Volleyball

The game of volleyball can be played by persons of different ability levels in recreational or competitive settings. It provides a cardiovascular workout and helps to build muscle mass through rapid muscular movements. While standing and sitting volleyball are the two main forms of this activity, adapted versions of volleyball include wallyball and water volleyball.

Adaptations on the game allow for greater participation by persons with disabilities. Players with amputations can participate with or without prostheses in standing volleyball (Fig. 54-22). “Wallyball” is another version of volleyball played on a racquetball court. With the proper equipment, water volleyball can be played in many indoor or outdoor swimming pools. Sitting volleyball is played with six players per team on a smaller court with a lowered net. This version of volleyball enables double-leg amputees and individuals with spinal cord injuries, polio, and various other lower-extremity disabilities to participate. In certain recreational volleyball settings, a beach ball or balloon can be substituted for a standard volleyball.

**FIGURE 54-22.** A sit volleyball player serves the ball. The use of prosthetic or orthopedic devices is not allowed in the sit volleyball competition. Courtesy of U.S. Paralympics, Courtesy of the Rehabilitation Institute of Chicago, and the National Center on Physical Activity and Disability ([www.ncpad.org](http://www.ncpad.org)).

United States Deaf Volleyball Association (USDVA) and the American Deaf Volleyball Association (ADVA) guide the game of volleyball for recreational and competitive players who are hearing impaired. Competitive standing and other variations of volleyball are played according to Federation Internationale de Volleyball (FIVB) standard international rules, with variations.

Resources: For more information, see the NCPAD fact-sheet on volleyball ([http://www.ncpad.org/competitive/fact\\_sheet.php?sheet=72&view=all](http://www.ncpad.org/competitive/fact_sheet.php?sheet=72&view=all)) and video clip on sit volleyball ([http://www.ncpad.org/videos/fact\\_sheet.php?sheet=510&view=all](http://www.ncpad.org/videos/fact_sheet.php?sheet=510&view=all)).

### Wheelchair Rugby

Developed in 1977, wheelchair rugby is a competitive game in which two teams of four players in wheelchairs attempt to maneuver the game ball over their opponent's goal line while in possession of the ball. Benefits include improved cardiovascular endurance, upper-body strength, mobility skills, and use of different muscle groups, as well as the opportunity to participate in an aggressive team sport combining strategy, power,

**FIGURE 54-23.** Wheelchair rugby players illustrating the intensity of competition. Courtesy of the Rehabilitation Institute of Chicago and the National Center on Physical Activity and Disability ([www.ncpad.org](http://www.ncpad.org)).

and quickness. The game is played primarily by individuals who have quadriplegia, as well as those with cerebral palsy or postpolio, with seven classification divisions that range from 0.5 to 3.5 points based on functional ability.

The game moves at a fast pace with aggressive players. Offensive strategies are designed to exploit defensive weaknesses (Fig. 54-23). Defensive strategies involve blocking, forcing turnovers, and intercepting or batting away the ball from the offensive team. Only the four wheels of the chair (and the antitip device, if applicable) may touch the floor during contact with the ball. A goal is scored when a player carrying a ball crosses over the opponents' goal line with two wheels. After a

goal is scored, a throw-in is used from any point on the end line to put the ball back into play. For more detailed information about quad rugby rules, consult the United States Quad Rugby Association Web site (<http://www.quadrugby.com/rules/rules2006.htm>).

Most rugby chairs have metal guards on the front, sides, and/or back of the chair to prevent opponents from hooking the chair during play. In addition, the wheels are attached at an angle (camber) for greater stability. Trunk, waist, leg, and foot strappings are allowed, depending on individual needs. Gloves and the use of taping at the forearms can protect against skin abrasions.

## CONCLUSION

The transition from rehabilitation to community-based physical activity is a critical one. There is a small window of opportunity for rehabilitation and health professionals to establish effective community-based physical activity recommendations that are more likely to be adhered to if the program meets the person's interest level, is readily accessible, and has an element of social engagement. The focus of this chapter was to provide professionals with the necessary resources to recommend tailored physical activity programs for individuals with disabilities. There are many types of physical activities that can keep people with disabilities engaged in this healthful behavior, including a variety of community-based fitness, leisure, and sport opportunities.

Most individuals recovering from an injury or health condition will appreciate the benefits of rehabilitation during the subacute period, but once the person returns home and stops performing certain rehabilitative exercises and increases his or her sedentary behavior, these gains are often lost or diminished and the risk of further health complications increases. Considering that generic physical activity programming not targeted to the needs of the particular end user is far less likely to result in long-term maintenance of health-promoting behaviors, a tailored approach is necessary for maintaining good adherence. The *PEP* model combines key factors including a person's motivational level (readiness to change), physical activity profile, health and mobility limitations, and barriers to participation, so that the rehabilitation and health professional can prescribe a program that meets each person's specific needs, interests, and circumstances.

Rehabilitation and health professionals play an essential role in connecting the patient/client to such community-based services. Armed with knowledge of the patient/client's disability, functional limitations, and health status, as well as

resources for encouraging various types of physical activities with appropriate adaptations and/or modifications, they can help transition the individual into a healthier lifestyle within a community-based setting. And as such, patients/clients maintain a physically active lifestyle. They will not only experience reduced secondary conditions and improved functional and health status, but they will also experience increased social integration leading to a higher quality of life.

# Performing Arts Medicine

*"The body says what words cannot."*

*Martha Graham, Dancer and Choreographer, 1894–1991*

## INTRODUCTION

Performing arts medicine is a branch of physical medicine and rehabilitation devoted to the care of musicians and dancers. A key concept of performing arts medicine is the ability to prevent, recognize, treat, and rehabilitate musculoskeletal injuries as related to each student, amateur and professional performing artist. This chapter discusses in further detail common injuries found in musicians and dancers, including injury management, rehabilitation, and barriers to care. The injuries primarily focus on the upper limbs for musicians and the lower limbs for dancers. Practitioners of performing arts medicine should have a solid understanding of musculoskeletal medicine and an appreciation for the physical effort and specific movement required to perform in each of the various arts.

## DANCE MEDICINE

Most current medical literature focuses on ballet (1–4). Research must therefore be extrapolated to treat other types of dance. The majority of this chapter focuses on the injuries associated with ballet, understanding that the performing arts practitioner treats all types of dance including modern, jazz, tap, folk, ethnic, ballroom, and hip hop, all of which can lead to medical problems (5,6). Each style places demands on the body and may vary with respect to footwear, dance surfaces, training, and alignment.

### Dance Training

Ballet training typically begins for female dancers by 5 or 6 years of age. Young dancers often begin training daily for 2 to 6 hours at a time with annual or semiannual performances by age 11 or 12. In order to pursue ballet professionally, pre-teen and teenage students with high-level ability and skills attend intensive summer programs, and those with the greatest ability and potential move to preprofessional ballet schools for year-round training. These exceptional students may participate in work-study programs with school in the morning, blended with class and rehearsals in the afternoon and evening. Some dancers obtain their general education degree early to

join professional companies, while others continue to dance through college and join companies later. A large component of a dancer's early career involves auditions. These tryouts can be critical to obtaining roles in performances and in the development of a professional career. Performing arts physicians need to acknowledge the high importance of auditions and should inquire about upcoming dates. This knowledge may aid in the decision to tolerate a higher risk of reinjury than under normal circumstances, as long as documentation of discussion and decision is thorough.

### Terminology and Positions

Knowledge about the technical requirements for dance is important. Performing arts medicine practitioners excel at understanding the biomechanical demands placed on dancers and the maladaptations many dancers use to compensate for inadequate anatomy, conditioning, or biomechanics. Dancers should be evaluated for onset of symptoms and triggers, in addition to demonstrating the movements or positions that reproduce the symptoms (7) (Fig. 55-1). Common dance terms are

*Plié*—heel remains on the floor with the knee in flexion (Fig. 55-2)

*Grand plié*—heels lift off the floor with deep knee flexion

*Pointe*—dancing on the tips of the toes, ankle in maximal plantar flexion (Fig. 55-3)

*Demipointe*—weight bearing on the metatarsal joints, ankle plantar flexion, and metatarsal joint extension (Fig. 55-4)

*Barre work*—dance classes are divided into three stages: *barre*, center, and movement from the corners across the floor. *Barre work* involves holding on to a bar during warm-up exercises and conditioning.

*Center floor work*—The second stage of a dance class performed in the middle of the studio involves balancing, jumps, and short sequences of movement.

### Causes of Injury and Risk Factors

#### Extrinsic

There are many common extrinsic and intrinsic causes of injury and risk factors in dance. One extrinsic factor is the type of dance floor. The presence of adequate shock absorption and the degree of surface friction can lead to injuries of the knee, foot, and ankle if there is too much surface resistance. Likewise, a floor that is too firm leads to fatigue and injuries such as tendonitis of the leg and foot (8).

**FIGURE 55-1.** The basic ballet positions of the feet: *first, second, third, fourth, and fifth.*

Footwear can also influence injuries. Most ballet dancers wear either slippers, composed of only fabric or leather and no structural support, or *pointe shoes*, which are made of a solid toe box, metal or wood shank, and fabric. Theoretically, *pointe shoes* act as an additional stabilizer of the foot as demonstrated by cadaveric studies (9). However, these shoes are not designed to provide adequate stability or shock absorption and have changed very little since the 1600s (4,8). Furthermore, principal dancers may wear out one to three pairs of pointe shoes per performance because if the shoe becomes too soft it can often lead to injury, such as tendonitis and stress fractures (9).

### Intrinsic

Intrinsic causes of injury or risk factors include, but are not limited to: malalignment of the lower limbs, muscle imbalance, and inappropriate training (7,8,10,11). Proper alignment in ballet is based on turnout (the maximal amount of external rotation at the hips), which will ideally enable a dancer to stand with the feet placed at 180 degrees in *first position*. Although dancers may appear to be able to achieve 160 to 190 degrees of turnout at the feet, they may not have the corresponding degree of external rotation at the hip (12,13). When the lower extremity is properly aligned in *first position* (14,15), the knee flexes directly over the foot. Many students will not be able to attain this ideal position and will compensate by forcing their turnout. “Rolling in” forces the feet into a position with a valgus heel and forefoot pronation (Fig. 55-5), leading to subsequent collapse of the medial arch and thereby increasing the torque on the ankle and knee (Fig. 55-6) (7,9,11). Young dancers, both female and male, will sometimes increase their lumbar lordosis in order to tip the pelvis anteriorly and thus obtain increased hip rotation. In addition to potentially leading to low back pain, other complaints may arise from the increased torque placed on the lower limb (7,11).

**FIGURE 55-2.** *Plié*—ankle dorsiflexion and knee flexion, performed in any of the basic positions.

Muscle imbalance is often due to inadequate strength or altered flexibility. Ballet emphasizes hip flexion, external rotation, and abduction, which can lead to weakening of the antagonist muscles (8). Deficits in strength and endurance at the hip may lead to injuries of the foot, ankle, and knee (21–23). Focusing the treatment on the injured joint without addressing any underlying hip muscle imbalances may frustrate both dancers and physicians alike as pain and dysfunction are likely to recur. By nature, dancing *en pointe* involves loading the ankle joint in maximal plantar flexion with accompanying distal pressure placed on the first and second toes. Significant ankle flexibility and intrinsic foot strength are required to maintain the position (9). Elite and professional dancers usually display appropriate alignment as such alignment problems typically extinguish careers prior to this level. Generally speaking, at the professional level, limb injuries more often result from overuse rather than from issues of alignment. In young dancers, immature skeletal formation may contribute to musculoskeletal injury. Similarly, growth spurts may further lead to muscle imbalances, where a gain of 1 to 3 in. in growth might overwhelm the muscular strength required to move and change positions. As a result, young dancers can develop muscle tightness relative to bone length and/or inadequate strength, particularly in the hip rotators (16).

The effects of inappropriate training are often related to factors such as excessive duration and intensity (7,10). As in other aesthetic sports that place a large degree of importance on the appearance of the performer such as diving and figure skating, dancers often have delayed menarche due to caloric restriction coupled with large amounts of exercise (17). As dancers are often subjectively judged on their appearance, eating disorders are common in preprofessional dance schools with some reports estimating up to 30% of the students being effected (18–20). Such behavior can often place dancers at increased

**FIGURE 55-3.** *Sur les pointes*, dancing on the tips of the toes in pointe shoes.

**FIGURE 55-4.** Demipointe—dancing on the metatarsals in either slippers or pointe shoes.

risk of developing the “female athlete triad”: disordered eating, amenorrhea, and osteoporosis (7,10).

### Incidence of Dance Injuries

In 2005, a UK national survey reported that 80% of 1,056 professional dancers sustained at least one injury per year (24). In a similar study of dancers at a sports medicine center, 90% of injuries occurred in the lower extremity and two-thirds were classified as overuse injuries (25). Of all the disciplines in dance, classical ballet necessitates the longest training, places the most physical demands on the musculoskeletal system, and studies indicate that 67% of all dance injuries occur from the practice of classical ballet (4).

### Common Dance Injuries

#### Spine Injuries

Dancers routinely suffer spine injuries similar to many other athletes, including but not limited to fractures of the pars interarticularis and sacroiliac dysfunction. Delay in the treatment of pars fractures may progress to fibrous unions that will not calcify and potentially result in spondylolisthesis. If underlying biomechanical issues are corrected within an appropriate time frame, dancers may continue dancing with spondylolisthesis. However, dancers should restrict activity with relative rest in the event of a new pars fracture and may require either an anti-lordotic modified Boston brace or a nonspecific conventional lumbar corset (26).

Sacroiliac pain occurs frequently and is often difficult to resolve (7,27). Jumping and leg extension on the affected side may incite pain in dancers experiencing sacroiliac dysfunction. Special physical examination maneuvers such as Gaenslen's

**FIGURE 55-5.** “Rolling in” of the feet, demonstrating collapse of the medial arch.

**FIGURE 55-6.** “Rolling in” at the knee, with tracking medial to the foot. This often occurs with insufficient hip external rotation strength and forcing of the physiologic barrier.

test and the Gillet's test are useful in diagnosis. Treatment of sacroiliac dysfunction may include mobilization of the joint and pelvic stabilization exercises.

Repetitive microtrauma from extreme extension or hyperextension may result in damage to posterior elements, such as the pars interarticularis, facets, pedicles, and spinous processes (28). Poor technique and control may cause painful injuries to the periosteum during hyperextension. Although this injury is painful, it requires no special treatment other than correction of technique unless it proceeds to pars fracture.

#### Hip Injuries

“Snapping hip” accounts for 50% of hip problems in dancers, occurring either medially or laterally with or without pain (4). When it occurs laterally, the iliotibial band or tensor fascia lata snaps anteriorly and posteriorly over the greater trochanter when landing from a jump in poor turnout and with excessive anterior pelvic tilt (7) or as the thigh moves between the anterior and posterior positions. “Snapping hip” may also occur medially and is sometimes referred to as “iliopsoas syndrome” (29) (Fig. 55-7). This phenomenon occurs when a hypertrophied iliopsoas crosses the femoral neck when bringing the hip into extension during a semicircular motion known as *rond de jambe* (7) (Fig. 55-8). A dancer with this injury will experience intense anterior groin pain during this arcing movement, particularly as the iliopsoas stretches over the femoral head from medial to lateral; it is also typically more painful while in the air than with the foot on the floor (30). “Snapping hip” rarely causes significant disability and responds well to

**FIGURE 55-7.** Painful arc zone. Dancers with iliopsoas syndrome experience a painful arc during *rond de jambe*, the circular motion of the leg from flexion through abduction to extension of the hip.

focused stretching, hip strengthening (especially the external rotators, adductors, and internal rotators), and antilordotic postural control (11,30). Other hip injuries such as labral tears, osteoarthritis, stress fractures of the femoral neck, hip avulsion injuries, and femoral neuropraxia have been described in the medical literature as well (7).

### Knee Injuries

Knee problems are often attributed to insufficient hip strength in external rotation or forcing greater foot turnout than physiologically possible (as noted previously). Hip weakness or alignment problems are the usual causes of knee pain. The typical sports-related knee injuries also occur in dancers, including anterior and medial collateral ligament sprains, patellar subluxation, and patellofemoral syndrome (31,32). Tears and injuries often result from slips, twisting falls, and improper landings from jumps. Diagnosis and rehabilitation of such injuries follow standard sports medicine guidelines.

### Acute Ankle Injuries

Ankle sprains are the most common acute dance-related injury (7). These sprains commonly occur when a dancer

**FIGURE 55-8.** *Rond de jambe en l'air*. For a dancer with iliopsoas syndrome, circling the leg with the foot in the air is more painful than *rond de jambe*, with the foot on the floor.

loses balance while landing from a jump while the foot is in plantar flexion. They can also occur from rolling over the lateral aspect of the foot while on *demi-pointe* (9). Interestingly, in full *pointe*, the ankle is relatively stable as the posterior lip of the tibia locks on the calcaneus and thus the subtalar joint locks in varus. It should be noted, however, that slight dorsiflexion relaxes the chain and may predispose the ankle to injury (10). As noted with other sports, the anterior talofibular ligament is the weakest ankle ligament and most susceptible to injury (9,10). The Ottawa ankle rules recommend ankle radiographs if a patient is unable to walk three steps or if there is tenderness over either malleoli (10). Specific rehabilitation of acute ankle injuries includes pool therapy, plantar flexion exercises, proprioceptive retraining, and peroneal strengthening with an emphasis on resuming full mobility of the talar, subtalar, and transverse tarsal joints (7,9).

### Overuse Ankle Injuries

#### Anterior Ankle Impingement

In anterior ankle impingement, the anterior distal tibia and the talus pinch the bony or soft tissue during ankle dorsiflexion, particularly during *grand plie* (7) (Fig. 55-9). The medical history is often notable for chronic anterior or anterolateral ankle pain on jump landings or a limited *demi-plié* (9). Other mechanisms and the source of pathology of ankle impingements are found in Table 55-1.

Physical examination might include an effusion, audible click, palpable tenderness, and limited dorsiflexion when compared to the contralateral side. Pain is also present with passive dorsiflexion when the knee is bent (9). This is primarily

**FIGURE 55-9.** Anterior ankle impingement during *plié* due to spurring.

a clinical diagnosis. Treatment includes restricting *pointe* and center floor work, encouraging exercises at the *barre*, non-steroidal anti-inflammatories (NSAIDs), local injections, modalities, and in refractory cases, arthroscopic surgery (7). Return to a *full plié* position may take 3 to 4 months (9).

### Posterior Ankle Impingement

Posterior ankle impingement is caused by the posterior tibia and calcaneus compressing the posterior talus and surrounding structures. This impingement may frequently be caused by a symptomatic os trigonum (7,9). The os trigonum is an accessory ossicle posterior to the talus which is often asymptomatic (11) (Fig. 55-10). When a dancer positions herself in extreme plantar flexion, the os trigonum is pinched between the tibia and calcaneus. Patients will present with posterior ankle pain, worsened with plantar flexion (11), and the pain and inflammation may limit the dancer's ability to perform *pointe*, as well as the movement from flat foot to *demipointe*. Os trigonum syndrome will also cause pain with both active and passive

**FIGURE 55-10.** Posterior ankle impingement due to an os trigonum.

**TABLE 55.1** Anterior Ankle Impingement Etiology

Site	Pathologic Change	Mechanism
Anterior talofibular ligament	Hypertrophic scar	Inversion ankle sprains
Soft tissue	Synovitis, tears	Plantar flexion
Anterior tibia	Osteophytes, traction spurs	Repetitive forced dorsiflexion
Distal tibia	Avulsion fracture	Rapid plantar flexion
Talar neck	Loose bodies	Rapid plantar flexion
Capsule	Calcium deposits	Forced plantar flexion

Modified from Motta-Valencia K. Dance-related injury. *Phys Med Rehabil Clin N Am*. 2006;17:708.

plantar flexion (7). This pain is usually posterolateral, behind the peroneal tendons and often with associated ankle stiffness (9). Diagnosis is again primarily clinical; however, a standard lateral view ankle x-ray can demonstrate the presence of an os trigonum (7). Magnetic resonance imaging (MRI) may also show bony edema of the distal tibia and inflammatory changes surrounding soft tissue (7). Treatment of posterior impingement syndrome includes dance training modifications including limiting *pointe-work*, NSAIDs, physical therapy modalities, and exercises, with the refractory case leading to surgical excision (7). Changing *pointe* shoe wear to a half or three-quarter shank to more easily facilitate *pointe-work* may also provide some relief (9).

### Achilles Tendinosis

Achilles tendinosis is classically seen in *pointe* overuse, excessive pronation and “forced turnout” during *plié*, or the wearing of too tight *pointe shoe* ribbons (10,11). Pain is localized to the zone of avascularity of the distal tendon, approximately 2 to 8 cm proximal to the insertion, and is often aggravated during landing from jumps (7). Physical exam is often notable for palpable tendon nodules, swelling, and crepitus (10). MRI and ultrasound are

useful tools for demonstrating tendon degeneration. Treatment includes gastrocnemius stretching, concentric to eccentric muscle strengthening, with approximately 25% of cases proceeding to surgical intervention to excise and debride the focal area of tendon degeneration (10). Stretch boxes strategically placed in the studio and theater have been shown to provide some degree of prevention for some dance companies (9).

## Acute Foot Injuries

### Subluxation

Cuboid subluxation may result in acute or chronic lateral midfoot pain (7). It is often associated with lateral ankle sprain injury (10) or is sustained during landing from a jump onto *demipointe* with the lower limb in external rotation (4). The medial border of the cuboid subluxes inferiorly, with dorsal displacement of the fourth metatarsal base, and plantar displacement of the metatarsal head (9,10). Physical exam is notable for tenderness over the cuboid bone, decreased mobility in passive supination/pronation, and a step-off of the fourth metatarsal head (10). A dancer may walk on the lateral edge of the injured foot as extreme supination is the most rigid position. Early diagnosis and treatment are key to preventing progress toward chronic injury. The cuboid should be immediately realigned using manipulation techniques (9).

Subtalar subluxation is caused by ankle hyperflexion, external rotation, and slight inversion, often occurs when performing *grand plié en point*, or landing from a jump on *demipointe* (33). Dancers may experience a sudden sharp talonavicular pain and a sensation of forward displacement of the foot, interfering with ambulation (7,33). Physical exam shows tenderness to palpation of the talonavicular ligament, anterior talofibular ligament, anterior tibiotalar ligament, posterior joint, and hypomobility of the subtalar joint (33). Imaging has not shown to be useful due to anatomic variation (4). Treatment includes manual reduction, taping, and relative rest for 6 weeks. Dancing may be started in a pool after the initial 2 weeks. Proprioceptive training may begin after 3 to 4 weeks followed by continued close observation (7,33).

### Metatarsal Fractures

Metatarsal fractures generally occur at the fifth metatarsal bone. These fractures are usually caused by missed landings and rolling over the lateral border of the foot on *demipointe* (9). Dancers present with tenderness, swelling, and ecchymoses over the fifth metatarsal bone, and lateral foot pain particularly with weight bearing (9,10). The most common proximal fifth metatarsal fracture is an avulsion fracture, which is commonly caused by an inversion injury (10). A “Jones fracture” involves the metaphyseal-diaphyseal junction, and often leads to nonunion due to the poor blood supply. “Dancer’s fractures” are oblique or spiral fractures of the middistal fifth metatarsal associated with twisting and inversion (10). Surgical intervention is needed for high-level dancers to avoid prolonged immobilization for Jones fractures and diaphyseal fractures (9,10). Avulsion fractures and Dancer’s fractures can typically be treated conservatively

and symptomatically with immobilization with a removable cast boot (9,10). Once fractures have healed adequately, rehabilitation goals return to strengthening the intrinsic foot musculature, retraining proprioception, initiating aquatic therapy, and gently returning to dance.

### Lisfranc’s Joint Dysfunction

Midfoot sprains most commonly involve injury to Lisfranc’s joint, where the second metatarsal articulates with the intermediate cuneiform. The Lisfranc’s joint is crucial to midfoot stability and the longitudinal and midfoot arches of the foot (9,10). This type of injury is typically caused by a loss of balance on *pointe*, or spinning and landing jumps which subsequently result in an inability to roll through *demipointe* or full *pointe* (9,10). Physical examination is significant for midfoot swelling, ecchymosis, and tenderness to palpation and pain with both passive pronation and supination (9,10). Imaging may reveal avulsion fragments or diastasis between the first and second metatarsal bases (9). Treatment depends on the severity of the injury, from non-weight-bearing cast immobilization to operative fixation if diastasis is present (10). However, a simple strain without evidence of instability should be treated nonsurgically (9).

Second metatarsal stress fractures at Lisfranc’s joint are almost exclusive to women practicing *pointe-work* (30). Ballerinas with long second toes are particularly vulnerable to Lisfranc’s fracture (34), as the load through the foot is carried mostly on the first two toes with partial weight bearing of the third toe. Studies implicate that the fully plantar flexed or hyperflexed forefoot places the highest risk of injury due to the anatomy of the Lisfranc’s joint (30), and increased load on a long second toe can thus lead to fracture at the base of the second metatarsal head or middle cuneiform bone (35–37).

## Overuse Foot Injuries

### Metatarsal Stress Fractures

Most stress fractures in dancers occur in the metatarsal bones (9). Multiple risk factors have been identified in placing dancers at risk for stress fracture including, but not limited to, long duration of practice hours per day and the female athlete triad (9). Early diagnosis improves outcomes (7), and dancers typically present with poorly localized midfoot pain initially after dance, but progressing to pain during activity and at night. Bone scans and MRI will reveal bone marrow edema and microfractures. Diaphyseal stress fractures are often seen with repetitive adduction, movements that involve cutting and pivoting. These fractures have poor healing potential due to their poor blood supply in the metaphyseal-diaphyseal region (9,10). Treatment of stress fractures involves immobilization or use of a removable cast boot with custom molded footplate for 6 to 12 weeks. The contralateral shoe may need to be modified, as a cast boot or footplate may cause a leg length discrepancy leading to sacroiliac dysfunction, and adjusting the height of the opposite shoe may help prevent imbalance and pain. Weight bearing is progressed as tolerated and aquatic therapy or Pilates

starting as soon as possible is recommended for approximately 6 weeks and until the fracture has healed. A padding system or toe cap for the second metatarsal and properly fitted *pointe* shoes may subsequently support the Lisfranc region, enabling a more balanced weight distribution (7).

### ***Flexor Hallucis Longus Tendon Dysfunction***

Flexor hallucis longus (FHL) tendon dysfunction is also known as “dancer’s tendonitis” (38). This condition often occurs with symptomatic os trigonum. The FHL is used as an accessory push-off muscle for *plié*, transitioning from flat foot to *demi-pointe*, and during jumps (30). These repetitive movements from full plantar flexion to dorsiflexion cause the FHL to become compressed within the fibro-osseous tunnel postero-medial to the talus with subsequent inflammation (9). Dancers present with pain when jumping and dancing on *pointe* and may have crepitus and triggering, or locking of the big toe in a flexed position much like a trigger finger of the flexor tendons of the hand (10). Physical examination may further reveal tenderness to palpation along the course of the tendon with painful passive extension of the big toe (7). Conservative treatment includes limiting *pointe-work* and jumps, correcting malalignments related to forced turnout, NSAIDs, physical therapy, and aquatic *barre* exercises (4,7,9).

### ***Sesamoid Disorders***

Sesamoid injuries occur in dancers due to the increased load on the sesamoid bones when rolling through *demi-pointe*, forcing turnout, out-toeing gait, and during abrupt landings (7). Sesamoids are located both in the tendon of the flexor hallucis brevis (FHB) and on the plantar surface of the proximal first metatarsal-phalangeal joint (MTP) and increase the mechanical advantage of the FHB. Dancers typically present with pain on the plantar aspect of the first MTP joint (10). Physical examination demonstrates tenderness to palpation of the sesamoid, pain with resisted MTP flexion, and restricted passive dorsiflexion (10). Injecting a small amount of local anesthetic can confirm the diagnosis (9). MRI can help differentiate bipartite sesamoids with smooth edges versus acute sesamoid fractures (9). Treatment is to correct alignment problems including avoiding excessive turnout, restricting *demi-pointe*, using sesamoid pads, wearing a stiff-soled shoe outside of class, physical therapy for mobilization of the joint, restoration of range of motion, balance/proprioceptive retraining and intrinsic foot strengthening, and occasionally corticosteroid injections (9,10).

### ***Hallux Rigidus***

Hallux rigidus presents as arthritic changes of the first MTP joint. Dancers experience pain at the first MTP joint with dorsiflexion, particularly on *demi-pointe*, which causes the dancer to roll onto the lateral metatarsals. Physical examination demonstrates tenderness to palpation of the first MTP, decreased passive dorsiflexion, and imaging may reveal osteophytes, joint space narrowing, or subchondral sclerosis (9,10).

Early treatment is usually conservative, including avoidance of *demi-pointe* and strengthening of the intrinsic foot muscles (9). While surgery may be an option, it may not lead to full restoration of movement, and some of these dancers may need to retire (9).

### ***Hallux Valgus***

Hallux valgus is a painful bunion on the medial border first MTP and is commonly exacerbated with *pointe-work*. Dancing in *pointe shoes* does not cause bunion deformities (9); however, the condition can be exacerbated by poor technique, inadequate shoe inserts, flat first MTP surface, and long second toe (4). Treatment includes orthotics for regular walking shoes, NSAIDs, modalities, and foot strengthening of FHL, adductor hallucis and flexor digitorum longus with the use of exercise bands to simulate releve, pushing the foot from *demi-pointe* to *pointe*, progressing to weight-bearing exercises (7), with surgery reserved for retiring professionals as intervention may lead to loss of range of motion (9).

## **Dance-Specific Rehabilitation**

Prevention remains the key in dance rehabilitation. Dance screening clinics may provide screening for adequacy of training, physical conditioning, malalignment, poor technique, prior injuries, and other medical problems (7). Ideally, dancers should be assessed in functional foot movements of plantar flexion, dorsiflexion, pronation, supination as well as *plié*, *demi-pointe*, parallel position, and at the individual affected joint (10). Much of dance rehabilitation is similar to sports medicine management including pain management, restoration of range of motion, muscle strengthening, and balance and proprioceptive retraining. Studies also indicate that supplementary physical conditioning or cross-training can both improve fitness and decrease injuries in dancers (39). Modification of dance activities may include strengthening initially in neutral position where the feet are in parallel position and not turned out, and then progressing from *barre* exercises to the center floor (10). Pilates-based exercises are often very effective for promoting balance and coordination (7) and enable injured dancers to remain relatively fit while recovering from injury. While acknowledging that improper technique may increase the likelihood of injury recurrence, rehabilitation should emphasize biomechanical reeducation, possibly with a transitional dance class supervised by both a specialized physical therapist and dance coach (7) or supervision with both a dance-medicine trained practitioner and dance instructor (30). Additional intervention may include psychological care for stress management, anxiety and coping with limitations, identifying proper shoes, nutritional assessment to screen for eating disorders, and advocating for general health improvement including smoking cessation (7).

The benefit of dance rehabilitation is cited in several studies (40,41). One study demonstrated savings in one ballet company of \$1.2 million over a 5-year period as well as a decrease in annual incidence of injury with the provision of in-house medical and therapy services (40). A second

retrospective cohort study conducted with the Alvin Ailey Dance Company revealed that comprehensive management inclusive of prevention, intervention, and case management, over a 5-year period, significantly decreased the number of worker's compensation cases from 81% to 17% and decreased the number of lost workdays by 60% (41).

## MUSCULOSKELETAL PROBLEMS IN THE MUSICIAN

Musicians of all ages and playing levels are susceptible to musculoskeletal pain and injury due to repetitive and unique biomechanical movement required to play an instrument. Many studies have reported the incidence of such injuries. The International Conference of Symphony Orchestra Musicians published a survey in 1988 that revealed 76% of 2,212 musicians had experienced an injury that affected their performance (42). A study of professional orchestra musicians in Puerto Rico published in 2007 revealed increased risk in younger musicians (ages 22 to 29) and older musicians (ages 50 to 61). Risk was also higher for females, increased playing time and technical difficulty (43).

Most of the injuries observed in musicians are similar to musculoskeletal injuries seen in the nonmusicians. It is imperative, however, to understand the biomechanics involved in developing these injuries in order to treat this population. In many cases, an isolated musculoskeletal injury can be career ending or life altering. In the last two decades, there have been numerous articles published on this subject. Terms describing musician-related injuries include overuse injuries, cumulative trauma disorders, muscle-tendon pain syndromes, playing-related musculoskeletal disorders, and strains. The incidence of specific injuries depends on the instrument played (Table 55-2). The remainder of this chapter reviews common musculoskeletal disorders in the musician organized primarily by body part. The emphasis is on risk factors and treatment unique to musicians.

For those not familiar with instruments and terminology, below is a brief overview (44):

*Woodwind instrument*—produces sound when the player blows against the edge of or opening in the instrument, causing air to vibrate within a resonator. These include the flute, piccolo, clarinet, bassoon, saxophone, and oboe.

*Brass instrument*—tone is produced by vibration of the lips, as the player blows into a tubular resonator. These include the trombone, trumpet, tuba, and the French horn.

*String instrument*—produces sound by means of vibrating strings. These include the violin, viola, cello, bass, electric guitar, bass guitar, acoustic guitar, harp, and banjo. The violin is the smallest of all the strings and the most common orchestral instrument.

*Percussion instrument*—any object which produces a sound by any action which causes it to vibrate and produce

sound. These include the snare and bass drums, cymbals, and in some references, the piano.

*Keyboards* such as the piano, organ, and accordion are sometimes classified in the percussion group and sometimes in the strings. For the purpose of this chapter, the term keyboards or the specific instrument is used.

*Embouchure*—position of the lips and tension of the face to produce a good tone on a brass or woodwind instrument.

## Disorders of the Head and Face

The temporomandibular joints (TMJs) connect the temporal bone to the mandible. TMJ disorder occurs when the surrounding muscles become hyperactive causing malocclusion or when the meniscus of the joint becomes displaced causing poor articulation (45). TMJ occurs in violin and viola players due to pressure on the mandible, clenching mastication muscles, and from vibrations transmitted from the instrument. It may occur in trumpet, trombone, and tuba players due to displacement of the mandible. Treatment includes modifying the shoulder rest, use of occlusal splints, and physical therapy. The goal of physical therapy is to increase joint flexibility and decrease muscle tightness. Modalities include ultrasound, TENS, massage, biofeedback, and myofascial spray and stretch (46).

Embouchure overuse syndrome is the most common performance injury suffered by brass players. Symptoms include lip pain, swelling, embouchure weakness, and lack of endurance. Chin bunching indicates embouchure fatigue or evidence of a problem in technique (Fig. 55-11). Rest is essential to recover from these symptoms. Once they improve, working with an appropriately trained music instructor to optimize technique and avoid excess strain can prevent further injury or even rupture (47). Louis Armstrong suffered a rupture of the orbicularis oris from repeated straining to play the trumpet. Surgical intervention is required if rupture occurs. A useful website for patients and clinicians is [www.embouchures.com](http://www.embouchures.com).

## Disorders of the Neck and Shoulder

Playing an instrument involves dynamic and static positions that can cause discomfort in the neck. Violin and viola players support the instrument between their left shoulder and left side of the neck and mandible. This prolonged static position can lead to myofascial pain and eventually, degenerative changes in the cervical spine. Cervical radiculopathy is more common on the left in violinists due to prolonged neck rotation and flexion (47). Support devices such as shoulder rests and chin rests can be used to optimize position. A properly fitted violin allows the player to turn his/her head and tilt it slightly to stabilize the violin. The hand is not required to support the instrument distally and the neck should not strain to hold it (Fig. 55-12). Neck pain can occur as the artist clamps the chin down on the chin rest to hold a poorly balanced instrument. The chin and shoulder rests are often placed too low, causing

the musician to raise her shoulder or thrust the head forward to compensate (47).

Keyboard players may develop neck pain from looking down at their hands, especially on the right side. Cervical radiculopathy is more common on the right side in pianists (48). Orchestra partners must keep their head turned to one side to read the music on the stand. The flute player is also at risk for cervical degenerative changes due to static position of

the tilted and rotated head. There is a mouthpiece available that has a 30 degree obtuse angle just past the lip plate. This allows for a near neutral position.

Shoulder injury is included in this section because many of the positions that contribute to neck pain also contribute to shoulder pain. Myofascial pain in the shoulder is common on the same side of the neck from positions described above. Rotator cuff impingement is likely

**FIGURE 55-11.** **A:** Normal long chin in embouchure formation. **B:** Moderate chin bunching as seen in fatigue or poor technique. **C:** Severe chin bunching, indicating overuse injury. Courtesy of Lucinda-Lewis of Embouchures.com.

in musicians that must keep their arms in a raised position with elbow pointing outward or forward. Instruments that require this position include the violin, viola, cello, and bassoon. In flute players, the right shoulder is more commonly

**FIGURE 55-12.** A violin that fits properly requires no hand support and does not strain the neck.

affected than the left because it is abducted and externally rotated (Fig. 55-13A and B).

The physician who treats musculoskeletal injuries is sure to see numerous patients with neck and shoulder pain. Current literature does not suggest that these problems are more common in musicians than in the general population, but when a musician presents with neck and shoulder discomfort, the instrument is usually the cause as it requires repetitive motion and unnatural positions. A study published in 2004 (49) in Sweden compared the risk of musculoskeletal injury in actors and orchestra musicians. The neck and shoulders were the most frequently injured anatomical areas and the prevalence of 25% was similar in both groups. The orchestra musicians, however, had a threefold to fivefold increased risk for pain affecting their performance capacity (49). Upper body strengthening and stretching to compensate for these postural asymmetries is helpful in these patients.

**B**

**FIGURE 55-13.** **A:** Shoulder abduction and external rotation required to play the flute may lead to impingement and shoulder fatigue. **B:** The flautist may drop the shoulder to avoid discomfort which strains the neck.

**FIGURE 55-14.** Playing an instrument in a slumped position contributes to tight anterior muscles such as the pectoralis muscles and scalenes.

### Thoracic Outlet Syndrome

Thoracic outlet syndrome (TOS) is a condition which may result in compression of the brachial plexus or subclavian vessels. This may cause paresthesias of the digits, vascular changes, and/or weakness of the hand. Musicians can be particularly susceptible owing to their need to maintain shoulder abduction or extension for prolonged periods of time (Fig. 55-14) (50). Musicians commonly have tight pectoralis and scalene muscles, which can cause compression of the neurovascular bundle. Irregular breathing patterns and breath-holding may be a risk factor in woodwind and brass instrumentalists (51). The presence of a cervical rib and the first rib are known contributors to TOS. It is imperative to stretch the tight anterior muscles and to strengthen the posterior scapular stabilizing muscles to treat this condition.

TOS has been reported to be more common on the left side in violin, viola, and guitar players, and bilaterally in flute and piano players. In one study, there was a 12% prevalence of TOS among musicians, most prevalent in pianists, string, and wind players (48). In an earlier study, the same author found that physical therapy to correct postural errors and range of motion was successful in 76% of 17 musicians with TOS (52).

### Disorders of the Arm and Hand

Entrapment of the ulnar nerve may occur between the two heads of the flexor carpi ulnaris in the cubital tunnel or in the bony sulcus between the medial epicondyle and the ulnar olecranon process. As in ulnar neuropathy of non-musicians, excessive elbow flexion is the most significant risk factor. It is more likely to occur in the left arm of viola, violin, and guitar players, due to continuous elbow flexion. Treatment consists of position awareness and limiting elbow flexion. This is not usually feasible while playing, but needs to be emphasized during other activities and sleep.

Medial epicondylitis occurs with repetitive wrist flexion, finger flexion, or pronation of the forearm. Medial epicondylitis occurs in the harpist on the left side. Lateral epicondylitis is due to repeated wrist extension, finger extension, or supination. It is more likely seen in clarinet players bilaterally and in oboe and trombone players on the right side. Percussionists and keyboard players are at risk for bilateral medial and lateral epicondylitis. Proper bench height is important to maximize a neutral wrist and elbow position. Forearms should be parallel to the floor when touching the keyboards (Fig. 55-15A–C).

Repetitive wrist flexion with ulnar deviation leads to DeQuervain tenosynovitis. This is an inflammation of the extensor pollicis brevis and adductor pollicis longus muscles on the radial side of the wrist. The clarinet, oboe, flute, keyboard, percussion, violin, and viola are the primary culprits. Use of a spica splint to immobilize the thumb as much as possible is helpful. A localized steroid injection provides relief in 81% of patients at 6 weeks (53). Ergonomics can be improved by repositioning the proximal arm so the left hand does not have to twist so radically to perform fingering work (Fig. 55-16).

Carpal tunnel syndrome (CTS), entrapment of the median nerve at the wrist, is the most common entrapment neuropathy in musicians (54). As in non-musicians, the primary risk factor is repetitive wrist flexion. Because CTS is such a prevalent disorder among the general population, causality from instrument playing is less clear than in other musculoskeletal disorders. Dawson studied 98 musicians with CTS and reported that only 18.4% had no risk factors for CTS other than playing music (55). Among right-handed musicians, the left hand in violin, viola, and guitar players is more likely to develop CTS. Treatment includes rest with splinting, icing, physical therapy and especially, technique modification (Fig 55-16). Fortunately, for musicians with CTS, over 90% have complete recovery with surgical and nonsurgical treatment (55).

The actual manipulation of keys, valves, and strings is performed mostly by the small intrinsic muscles of the hands (56). The intrinsic muscles include the thenar, hypothenar, interossei, and lumbrical muscles. Involvement of these small muscles is less studied and referenced in the literature. Dawson, however, addressed this problem in a retrospective chart review of 1,354 instrumentalists with hand and upper extremity injuries, 51 of whom had strains of hand intrinsic muscles. Risk factors included playing keyboards, string instruments, female sex, and higher-level musicians. It is hypothesized that females are more affected due to smaller, and therefore, weaker hand muscles (56). Treatment includes relative rest, modification of technique, analgesics, and occupational therapy, which can address ergonomics of playing.

### Disorders Related to Joint Laxity

Many authors have described joint laxity as a risk factor for injury among musicians. Brandfonbrener found that 34% of 128 musicians presenting with arm and hand pain had hyperlaxity, which appeared to play a role in the etiology of pain (57). Many joints can have hyperextensibility. Having more than 10 degrees beyond 180 degrees of proximal interphalangeal

A

B

**FIGURE 55-15.** **A:** A low bench causes the wrists to be maintained in extension. Also with a low bench, a pianist may shrug shoulders to maintain neutral wrists which strains the trapezius, neck, and shoulders. **B:** A high bench causes the wrists to be in flexion and adds stress to the fingers. **C:** Proper bench height allows neutral position of the shoulders, elbows, and wrists.

C

joint extension and/or 10 degrees or more beyond 90 degrees of metacarpophalangeal joint extension seems to put musicians at most risk (58). More women than men have joint laxity. Smaller hands are also a risk factor for hand injury in musicians, thus the clinician should be especially vigilant when dealing with hand pain in women musicians (58). Awareness, education, supportive splints or taping, and joint protection are the cornerstones of treatment (Fig. 55-17).

### Disorders Related to Focal Dystonia

Focal dystonia is characterized by involuntary muscle contractions that selectively interfere with the execution of specific motor tasks such as writing or playing a musical instrument (59). Similar to writer's cramp, a focal dystonia of the hand, dystonia may affect the fingers of instrumentalists and more rarely, the embouchure in wind instrumentalists (60). The dystonia

causes the finger or lip to contract when it should not, or otherwise move involuntarily (Fig. 55-18). Lederman found a pattern of involvement of the left hand in string players and the right hand in keyboard and wind players (61). Keyboard players appear to be most commonly affected of all instrumentalists, usually involving the fourth and fifth digits of the right hand which plays melody more than the left hand (62). Dystonia of the fourth and fifth digits may be more common in patients who have developed ulnar neuropathy (62).

A study of patients with focal hand dystonia suggested that these patients have alterations in the cortical somatosensory representation of the digits. The representation of the fingers spans outside the area normally occupied in persons without focal dystonia. This may affect sensorimotor feedback and cause involuntary co-contraction of other muscles (63). The onset is insidious and usually painless (64). It should be

**FIGURE 55-16.** **A:** Poor glenohumeral joint motion restricts arm position and generates poor wrist ergonomics. **B:** By increasing glenohumeral motion, the hand is positioned with less wrist deviation.

considered when a musician begins to experience difficulties with speed and precision of playing and when he or she has to work harder to play. It is helpful for the examiner to observe the musician playing and watch for subtle signs of slow, hesitant, or abnormal movements of fingers or lips (65).

Treatment of focal dystonia is challenging. An evidence-based review by the American Academy of Neurology in 2008 concluded that botulinum toxin is potentially effective in the treatment of focal upper limb dystonia (66). Priori et al. found that immobilization of the forearm and hand for 4 to 5 weeks resulted in improved function (59). The hypothesis is that immobilization leads to plastic changes at the motor cortical level, reducing excitability. Unfortunately, treatments are not always successful and in more than half of the musicians with dystonia, it is career ending (67).

### Upper Back Pain

Myofascial pain commonly occurs in the trapezius, levator scapulae, and periscapular muscles. As in the general population, it is caused by maintaining a static position, poor posture, and muscle fatigue. The tendency toward counterclockwise

**FIGURE 55-17.** **A:** Postpregnancy hyperlaxity at metacarpophalangeal (MCP) joint. **B:** Orthosis fabricated to prevent abnormal MCP joint motion. **C:** Functional hand orthosis preserves hand movement but limits hyperlaxity.

rotation of the guitarist's spine facilitates right shoulder protraction and placement of the strumming hand. Widening of the strap can help decrease tension on the left trapezius and periscapular muscles (68). The physician may offer trigger point injections or make a referral to physical therapy for myofascial release and neuromuscular therapy, but restoring postural symmetry, strength, and flexibility is again the crux of treatment.

**FIGURE 55-18.** Focal dystonia in the left fourth and fifth digits. The affected fingers flex off the keys out of the musician's control.

### Low Back Pain

An important risk factor for muscular strain in the low back is maintenance of a position in which the weight of the spine is not well balanced (69). This is a likely scenario in many musicians. A discogenic etiology of pain is more likely with lumbar flexion. Musicians who play leaning forward, especially while seated, are likely more at risk for disc bulging and degenerative disk disease. Lifting and carrying heavy instruments is also a risk factor for muscular strain and discogenic pain. The clinician should recommend wheeled carts to transport heavier instruments, for instance, the harp, drums, and bass (42).

The practitioner and music instructor should focus on the posture of the musician while playing. Paull and Harrison, authors of "The Athletic Musician," recommend a chair designed specifically for musicians with the front end sloped and the rear horizontal (70). This puts about one-third of the body weight through the feet, taking the weight off the spine (70). Similarly, a wedge cushion can be added to a standard chair. If using a standard chair, it is best to have the legs parallel to the ground and the back straight (Fig. 55-19A and B). It is helpful for guitarists to have a footstool so that he/she can rest the guitar on the elevated thigh. A string player with low back pain may improve symptoms by playing standing up, though the technique is different. A strap can be added to support the guitar while standing.

### General Guidelines for the Treatment of the Injured Musician

It is widely accepted that athletes should undergo proper strengthening, conditioning, and stretching to maximize their performance. The musician is using smaller muscles to perform, but ignoring the basics of maximizing function and performance can have devastating results. The physician, therapist, and music instructor should reinforce the need

**A**

**B**

**FIGURE 55-19.** **A:** Without foot support, the guitarist maintains lumbar flexion. **B:** Elevation of the foot on a stool allows a more neutral lumbar position.

to address muscular weakness, tightness, and asymmetries. Emphasizing a healthy lifestyle, incorporating diet, regular exercise, abstinence from tobacco, and avoiding excessive use of alcohol are also essential. In comparison to athletes, musicians are more likely to be deconditioned, and the clinician should inquire about exercise habits. The impact of physical problems may be exacerbated by the stress of performing, thus referral to a psychologist may be indicated.

Novice musicians should gradually increase their practice time and rest at appropriate intervals to avoid muscle fatigue. There are several suggested guidelines such as 5 minutes of rest for every 20 minutes of playing, 10 minutes of rest for 50 minutes of playing, and 10 to 15 minutes of rest for 30 minutes of playing (51). During rest, the musician should stretch and change positions. An abrupt increase in practice time is the most important risk factor for playing-related musculoskeletal disorders (71).

Communication with the music instructor and musician is essential to optimize performance. Together, they can assure proper instrument size, adjustment pads, benches, straps, and harnesses. Most of the problems discussed can be prevented with education regarding posture, technique, and instrument specific conditioning.

### Barriers to Treatment of the Performing Artist

Barriers to care often include lack of medical insurance or financial coverage. Worker's compensation is usually only found in large dance companies or in the university setting for dancers. Similarly, worker's compensation and health insurance are often unobtainable for musicians. The median hourly wage for musicians and singers in 2007 was \$19.92, and it is rare for them to have guaranteed work beyond 3 to 6 months (72). Physical therapy, occupational therapy, physician visits, medications, and durable medical equipment may be unaffordable.

It is necessary to prescribe rest at times, which in many cases, results in lost income. There is often pressure from parents or managers of dancers and musicians to continue through the discomfort. More seasoned musicians may choose to perform injured during their busy seasons and audition periods when they are in the most need of treatment and rest.

### CONCLUSION

Musicians and dancers are a wonderfully unique group of people. Knowledge of the body mechanics required to play an instrument and dance, and the accompanying lifestyle is vital to optimize the outcome of musculoskeletal problems. A reference for current concepts in performing arts medicine is the Performing Arts Medicine Association (PAMA) at [www.artsmed.org](http://www.artsmed.org).

### ACKNOWLEDGMENTS

We would like to acknowledge the following individuals for their help with this chapter: Konrad Weatherhogg, PT for assistance with rehabilitation techniques; Stephanie Levi, PT, for sharing her library of arts medicine articles; the music department at Charlotte Christian School—Don Humphries, Kelly Goley, and Jane Mendlik for being our musician models, and Laura Goodyear and Terry Efird, Charlotte Christian School for facilitating our photography session.

# Children with Disabilities

The rehabilitation of children with physical impairments in some ways resembles and in many ways differs from that established for adults. It is a challenging combination of normal child care and the best of rehabilitation intervention strategies. Successful rehabilitation interventions require the understanding that a child is not merely a miniature adult, and that specific physiologic parameters exist that either complicate or allow unique intervention opportunities. This chapter reviews the scope of disabling disorders that occur in childhood, the specific differences between children and adults that relate to their special needs, and the basic principles of management of disabled children. The specific management of various childhood disorders will be found both within this chapter and within relevant sections of other chapters.

The various disabling disorders that occur in childhood may be characterized as congenital if they are acquired before birth and are not due to known external environmental factors during the birth or postbirth period. Otherwise, conditions are considered to be acquired. Congenital problems may be further specified by cause as either genetic or influenced by some extrinsic factor, even though the effect was expressed in the prenatal period (e.g., fetal alcohol syndrome). Acquired disabilities usually are the result of trauma, infection, or other causes.

Developmental disabilities in children exert a major impact not only on the child's ability to function in the family and in society, but they also result in 1.5 more doctor visits and 3.5 more hospital days per year than for nondisabled children of similar age. In addition, these children typically lose twice the number of school days annually, and there is a 2.5-fold increase in the likelihood of repeating a grade in school when compared with the general population of children. This impact is much greater in children with multiple disabilities or with either cerebral palsy (CP), seizures, delays in growth and development, or emotional or behavioral problems (1).

## THE PEDIATRIC PATIENT: DIFFERENCES TO CONSIDER

Knowledge of the patterns of growth and development is key to understanding, anticipating, and managing the difficulties that disabled children experience. In the child's early years, head circumference, weight, and height are important parameters to

monitor. Standard tables of growth and development may be used to record and compare disabled children with the healthy population (Tables 56-1 to 56-3).

## Physiologic Performance

Children change with age and size in a number of physiologic parameters. Normal heart rate, respiratory rate, heat transfer behavior, and various chemical assessments all change as a function of age. For example, serum alkaline phosphatase levels may be elevated compared to adult reference values in an adolescent not because of the presence of occult heterotopic ossification but rather because of normal accelerated bone growth.

The question of enhanced neural plasticity in youth remains open. Conflicting data appear in the literature to support or reject this concept, but the clinical management implications are generally well accepted: the more treatment that is administered earlier after disease onset and at a younger age, the better the outcome seems to be.

A number of neurologically mediated reflex behaviors are age and development dependent. For example, the asymmetric tonic neck reflex (ATNR) (Fig. 56-1) is a normal behavior when elicited at 2 to 6 months of age, but may be distinctly abnormal when it is persistent and dominant many months later.

## Primitive Reflex Patterns

Because they are more commonly observed in children with physical disabilities, the major primitive reflex patterns that may either interfere with or facilitate skilled motor actions should be well understood. The times of appearance and disappearance of these reflexes in the developmental sequence are summarized in Table 56-4.

The most basic proprioceptive patterns are the flexion and extension synergies of the upper limbs and lower limbs. In the upper extremity, the full flexor pattern is more commonly seen in CNS lesions, while in the lower limbs, extensor patterns are usually seen. Upper extremity flexor patterns include shoulder adduction, flexion, and internal rotation with elbow flexion, wrist pronation and flexion, and finger and thumb flexion (Fig. 56-2). The thumb is frequently tightly adducted and flexed into the palm. The extension posture of the lower limb includes hip adduction, extension, and internal rotation, along with knee extension, internal tibial rotation, and equinovarus foot posturing (Fig. 56-3). In both these postures, the fingers

and toes appear to be influential in establishing the dominance of one or the other posture. It is frequently noted that forcing the toes into extension will facilitate a full flexor synergy of the lower limb. Similarly, placing the flexed thumb in an abducted

and extended position will frequently facilitate a full extensor response in the upper limb.

Lateral rotation of the head on the trunk produces the ATNR (see Fig. 56-1). This is the classical fencer's posture of extension in the upper and the lower limbs on the nasal side, and flexion of both limbs on the occipital side. The symmetric

**TABLE 56.2** Examples of Gross Motor Milestones for Comparing Disabled Children with the Normal Population

Age	Activity
2 mo	Head in midline
3 mo	Prone prop on extended elbows
4 mo	Rolls prone to supine

tonic neck reflex (Fig. 56-4) describes midline effects of flexing and extending the head on the body. Flexion of the neck facilitates flexion in the upper limbs and extension of the lower limbs. Extension produces the opposite pattern.

The vestibular system mediates static postures and dynamic postural reactions. These are important movement

**FIGURE 56-2.** The flexor synergy posture in the upper extremity.

patterns that facilitate the development of mobility skills. The most commonly seen static vestibular pattern is the tonic labyrinthine reflex. This pattern, facilitated by the supine position of the head, demonstrates lower extremity symmetrical extension with upper extremity shoulder abduction and external rotation. In the prone position, shoulder adduction and internal rotation are accompanied by lower extremity flexor posturing.

Cutaneously mediated reflex patterns include palmar and plantar grasp, elicited by tactile pressure over the respective sites. In young infants, the stepping response is an example of a kinesthetic reflex and is seen as a result of loading one limb (e.g., by vertical suspension) and stimulating the dorsum of the opposite foot, which is presumably a cutaneous influence as well. The positive supporting reaction occurs pathologically in older children when a loading of the suspended child's plantar surface results in a symmetric extension pattern of the lower limbs.

### Child Development

In any assessment of children, one cannot overemphasize the importance of measuring performance against age-expected norms. An understanding of all areas of normal development is essential if an abnormality is to be recognized (2,3).

**TABLE 56.4** Normal Acquisition and Regression of Primitive Reflex Behaviors

Reflex	Age of Onset	Age Reflex Disappears
Moro	Birth	6 mo
Palmar grasp	Birth	6 mo
Plantar grasp	Birth	9–10 mo
Adductor spread of patellar reflex	Birth	7 mo
Tonic neck	2 mo	5 mo
Landau	3 mo	24 mo
Parachute response	8–9 mo	Persists

**FIGURE 56-3.** The extensor synergy posture in the lower extremity.

### Psychosocial Development

Frequently, children may be infantilized by family and caretakers as a response to guilt or pity for the child. Conversely, some may be assumed to be more mature than is really the case, particularly if much time has been spent in the company of adults in hospitals and other health care settings.

Children who grow up with a physical limitation usually do not have a sense of loss of ability. It is usually around adolescence, when social sensitivity and maturity cause adaptation problems to surface. In the early years, it is important to help the child and family identify the child's strengths and abilities so that, despite the disabilities, a sense of confidence and self-worth can be built (4).

### COMMON CONCERNS IN TREATING DISABLED CHILDREN

Although the disabling disorders of childhood are widely varied, they share a number of common medical issues and potential as well as active problems. These will be discussed below as well as

**FIGURE 56-4.** The symmetric tonic neck reflex.

under specific clinical conditions. Routine well child care should not be overlooked, with careful attention paid to monitoring of growth parameters, nutrition, and especially immunizations, since the more seriously ill child may slip through the cracks of the well child system and fall behind in immunizations. Due to their particular susceptibility to infection, pneumococcal and influenza vaccinations should be given routinely.

Additional areas of medical concern will be reviewed under appropriate sections of specific clinical conditions as they differ somewhat in their presentation and treatment approach. These include spasticity and the various orthopedic conditions of contractures, scoliosis and hip dysplasias (5), bowel and bladder incontinence, decubitus prevention, and gastroesophageal reflux.

Functional issues are common to many diseases and disabilities. Specific management strategies vary with the particular disease, but the determination of goals and objectives is largely independent of the specific disease.

The desire and ability to communicate is the highest priority in managing a child with a disability. This allows the child to interact with his environment in spite of what may be profound physical impairment. Communication need not be vocal in nature to be effective. Gestures and signs may be used if motor control allows. As simple a movement as control of eye gaze may allow use of assistive devices as primitive as object boards to as sophisticated as computer-assisted voice output devices. What is important is not the technology but the identification of the potential for communication and the development of a system that allows a child to live up to his or her potential.

Second to communication in priority is the child's ability to control his or her motion in three-dimensional space. Frequently, children are provided with passive transportation instead of the technical ability to achieve independent mobility. From a developmental perspective, newborns start experiencing self-directed movement in space in their cribs, and a child who is crawling and creeping is acquiring substantial knowledge about the world by navigating within it. It is important not only to provide convenient transportation for parents but also to give the child control over his or her own mobility. As in communication, the devices used are dictated by whatever movement control the child demonstrates. Early prone mobility may be facilitated by wheeled prone boards, while once the child can be positioned in sitting, this can be replaced by caster carts and later by appropriately designed wheelchairs. For the child who is unable to propel a manual wheelchair, there are powered vehicles. Limited research has supported clinical observations regarding the age at which a child can control a powered wheelchair (6). By 18 months, the child may be able to acquire the eye-hand coordination necessary to control a wheelchair with a joystick. More sophisticated steering controls such as wafer, head or mouth switches require more advanced developmental levels. For the child with ambulation potential, lower extremity orthotics provide optimum positioning of pivots for safe gait, while upper extremity assistive devices may provide necessary stability.

The more severely impaired children frequently need adapted seating and positioning systems to achieve a number of developmental goals. General goals include normalization of tone, symmetric positioning, and improved trunk alignment. This often facilitates use of the head or upper limbs for communication, self-care, and educational activities. Side-lying devices may facilitate function and maintain trunk flexibility for floor and bed-level activities. Adapted seats are useful for spasticity management and the facilitation of upright activities. Car seating that is safe from both a postural and a crash safety perspective gives secure travel capacity to the child and family. Standing devices allow vertical alignment, weight bearing, and experiences in the upright posture although the effectiveness in reducing osteoporosis has not been shown.

### Self-Care Activities

Appropriate goal setting is most important. Infantilization will often limit the achievement of the child's potential. However,

unrealistic goal setting should also be avoided. Few methods for the quantified assessment of functional abilities in children exist.

### Education

Whereas vocational rehabilitation is an important consideration for the adult with a disability, special education is important to the child with a disability. The laws and services for children with disabilities vary with state and local school systems, but some common features are present. According to federal law (PL94-142 and PL99-457), the goals of special education are to provide "free and appropriate public education" in the "least restrictive environment" for a child. Part H of PL 99-457 mandates that participating states also provide early intervention services for children with developmental disabilities from birth to 2 years of age. Services that may variably be incorporated into this type of educational program include special education, physical therapy, occupational therapy, speech and language therapy, adaptive physical education, psychological and social work services, and nursing services. In each case, these services become school system responsibilities in that they are necessary for the child to participate in an individualized education program, a specific educational plan with goals, objectives, definition of services, and time frames.

The role of health care professionals in the special education system is an advisory and participatory one. Programs developed within a school setting should be consistent with those established out of school, in both the home and other therapy settings. School programs should not let therapeutic goals obscure their educational objectives. Programs that effectively integrate medical rehabilitation needs with those of education are the most effective (7).

### Play

Children with disabilities frequently need special assistance in achieving the ability to play successfully. Recreational therapy, music therapy, art therapy, play therapy, and other interventions may be helpful in allowing a child to find mechanisms to express himself or herself and to experiment with future skills and roles.

Adapted toys and games are useful. Battery adapters that allow external switch control of any electric or electronic device may give the child with a severe disability the option to play with age-appropriate toys while possessing only limited physical skill.

Children also may need special assistance in experiencing group play. Participation in nursery school programs, play groups, and other endeavors will allow the child to experience play with other children both with and without disabilities. Parental counseling and resource identification may be necessary to facilitate these activities.

### Social Skills

Children with disabilities are often found to be deficient in adaptive social skills because of a variety of factors, including

limited normal childhood experiences and relatively more intensive involvement with the health care community. Efforts may need to be taken to assist a child and family to identify specific behavioral issues and find methods to overcome them. The concept of a child having acquired learned helplessness is useful as a perspective for parents and health care professionals in dealing with these issues.

As these children reach adulthood, they frequently remain in the home setting with their parents long after most young adults have elected to live independently. They also demonstrate a much higher rate of unemployment than their nondisabled counterparts (8).

### Parenting Skills

Just as normal child parenting is a challenging experience, so too is parenting a child with a disability. It is further complicated by the challenges of health and social impairments experienced by the child and family. Many parents need assistance and guidance in coping with what are really normal parenting issues in their care for the child with a disability.

Common problems include discipline maintenance and difficulty in setting appropriate levels of expectation of responsible behavior. It may be helpful to counsel the parents on how to distinguish the special limits and expectations that are appropriate for the disability from normal parenting issues, such as control and authority challenging. Introducing families to parents of other children with disabilities is also a very positive strategy.

### Sexuality

Managing the emerging sexuality of a child with a disability requires knowledge, an openness and willingness to discuss, and anticipatory strategies. Many of the early needs of these children are simply for accurate and age-appropriate information about sex and reproduction in general, as well as the child's specific abilities or limitations based on the disability. Frequently, knowledge about the child's sexual and reproductive potential is also needed by the parents.

Education and counseling for the adolescent child are often necessary. Children may express their underlying sexual concerns through other behaviors, including social withdrawal and depression. A high index of suspicion of the need for sexual education and counseling should be maintained by the involved health care professional.

### Independent Living

A long-term perspective on the child's potential to live independently should be adopted from an early age. Realistic goal setting is the essential first step for any long-term rehabilitation program and for attaining independence. It is frequently possible to distinguish at an early age the child who will need some type of supported living situation in the long term. Helping the family and school system to identify these expectations early on will facilitate appropriate school programming and long-term planning.

It is unfortunately all too frequent that one encounters a seriously developmentally disabled adult 30 to 40 years of age who lives with his or her parents until the parents become infirm

or die. Many times there has been inadequate planning for legal, estate, and practical matters that suddenly become crises. The solution to these types of problems is prevention by ensuring that they are anticipated long before they become a reality.

## EVALUATION OF THE CHILD WITH A DISABILITY

There are several objectives to be achieved in the evaluation of a child with a disability.

First, one should determine the type and etiology of the disability. This is based on a careful history and physical examination, including careful assessment of all areas of development from birth to present. Review of previous medical records and evaluations by other members of the rehabilitation team may be helpful. Next assess the child's potential to benefit from rehabilitation services. In addition to biologic potential, outcome may be affected by the family's adjustment to their child's disability and their ability to support the therapy program.

### Evaluation by the Physician

It is essential that the physician establish rapport with both the child and family members present. Young children are typically frightened by any encounter with health care personnel. The most critical factor in obtaining useful data from the initial history and physical examination of a child is the development of a cordial relationship with the child and family as early and rapidly as possible during the interview process. The environment in which the examination is conducted must be as nonthreatening as the demeanor of the physician. Toys and children's artwork are useful tools in creating such an atmosphere. The physician should present as much of a friendly image to the child as possible. Attention to seemingly unimportant factors such as not wearing a white coat in the child's presence and sitting while examining or interviewing the child can have a major impact on the development of a cordial relationship. Other helpful measures include smiling frequently and assuring the child that he or she is not in your office to receive shots from you. If size permits, use the parent's lap as the "examining table." In the history, a careful review of the pregnancy and birth history as well as the family history is essential. In children with acquired disabilities, detailed information about the illness or injury that produced the disability should be obtained. A detailed developmental history should be elicited. Comparing the development of the child with a disability to other healthy children in the family often facilitates this process. The administration of standard developmental assessment tests adds valuable information in identifying the specific areas of developmental delay in all functional areas.

The initial physical examination should be brief with as much of the examination as possible conducted by observation of the child. Much of this can be accomplished while taking the history. Everything the child does is a hint to their developmental levels in all areas of performance. Actual physical contact

can be kept to a minimum. Considerable data regarding basic motor skills such as head and trunk control, reciprocal creeping, standing balance, and gait patterns can be obtained in this manner. Quality of movement can be easily assessed and may actually be more reliable than when performed upon request (i.e., the “doctor walk” of the mildly affected CP child). Toy play may allow observation of fine motor skills as well as the ability for imaginative play and social interaction.

Assessment of the developmental reflex profile should be performed. Manual muscle testing is usually not possible in a child less than 5 years old. Observation of an infant’s spontaneous movements as well as of the child during play provides the examiner with information about antigravity muscle strength. Muscle tone should be assessed not only for the degree of tone (i.e., low, normal, or high), but also for the pattern of tone and what activities may trigger abnormal tone. Significant fluctuations in muscle tone should be noted along with a description of factors that seem to cause the fluctuation. For example, in children with spasticity, a marked increase in tone of a given muscle may be produced by a sudden stretch of that muscle or its tendon. In children with athetoid CP, tone fluctuations may be produced by startling the child with an unexpected touch or loud noise.

Deviations from normal range of motion in any of the limbs should be recorded. In cases where limitation of range of motion exists, the family should be questioned regarding their observations as to whether such tightness is static or progressive and approximately how long it has been present. Monitoring of height, weight, and head circumference is an important routine assessment. Use of the normative charts for comparison purposes is appropriate. Significant deviations in the pattern of growth should be noted and explained. Difficulties in growth may be the result of chronic illness, nutritional deficiency, or chronic gastroesophageal (GE) reflux, along with a host of other specific problems.

In children of school age and above, the sensory examination including vision and hearing can usually be completed successfully. In younger children and particularly in infants, the sensory examination will primarily consist of the child’s response to noxious stimuli such as a pinprick. The response is usually crying and/or withdrawal.

Sensorineural testing in children under 4 years of age is usually limited to simple screening examinations due to the inability of the child to provide consistent responses to testing. The child’s ability to follow objects with his or her eyes combined with observation of spontaneous eye movements or their absence can assist the physician in determining whether more definitive testing is needed. The child’s ability to respond or localize sounds can help to make similar determinations with regard to hearing. Vision and hearing testing in infants and younger children suspected of abnormality in these functions will require the use of sophisticated measurement devices by physicians specializing in those areas. Auditory and visual brain stem response testing has proven to be very useful in assessing these functions in children too young to respond to standard screening tests. Older children can be screened for visual and auditory function using the same testing techniques used for adults.

Instruments used in the neurologic examination such as reflex hammers and tuning forks should be shown to the child before they are used. It is often helpful to allow the child to play with them before the testing.

The data obtained at the initial evaluation may be synthesized using various tools described below and used as a basis for future comparisons during the treatment process as the child grows. Commonly used screening tests for developmental assessment include the Bailey Scales of Infant Development, designed for children from birth to 30 months and the Denver Developmental Screening Test. Both are easy to perform but are relatively insensitive to increments of developmental progress that may occur in children with severe disabilities.

Quantitative analysis of motor performance of children is accomplished by several strategies. First is the measurement of physical parameters, such as range of motion and strength, and physiologic parameters, such as heart rate and respiratory rate. Timed trials of specific activities, such as the Jebson Taylor Hand Function test, may be useful as norm-referenced comparisons or sequential performance reassessments.

Quantitative descriptions of the functional activities of children with disabilities are essential for monitoring and planning rehabilitation programs. The few pediatric tools currently available include the WeeFIM (9), the gross motor functional measure (GMFM) (10), and the Pediatric Evaluation of Disability Inventory (PEDI) (11). In addition, the analytic tool for children with spina bifida described by Sousa and colleagues and the generally useful Tufts Assessment of Motor Performance (TAMP) may be used. The TAMP provides a method for structured quantitative description of developmentally oriented activities that are commonly performed by children with serious disabilities.

## The Rehabilitation Plan

Once the initial evaluations are completed, rehabilitation goals and a comprehensive management program should be developed at staffing conferences, involving as many members of the rehab team as possible (PT, OT, ST, teacher, social worker, psychologist, nutritionist, nurse, etc. and especially the child and family). Often, however, services are delivered at distant sites and face-to-face conferencing may not be practical. Written, telephone, and even e-mail communication among treating professionals helps coordinate the therapeutic approach and avoids sending “mixed messages.” The involvement of the family in daily carryover of treatment strategies is vital.

## Prediction of Outcome

One of the major responsibilities of the health care professional is the establishment of medical and functional prognoses for a child with a disability. From these estimates of outcome, the specific objectives and plans of management can be formulated that will guide the daily activities of the child and family. It is therefore most important to both accurately predict prognosis and at the same time be cognizant of the limits of predictability for any individual child. In general, it is important to emphasize the importance of cognition and communication over

ambulation. Discussion of the child's strengths as well as weaknesses is vital. Even for the most severely impaired child, comfort and a stimulating environment should be the minimum achievable goals. The correct approach is to admit uncertainty when it exists, make cautiously optimistic predictions, and move forward with goals that at least provide for comfort and care for both the child and family.

## SPECIFIC CLINICAL CONDITIONS

### Cerebral Palsy

CP is a disorder of movement control and posture resulting from a nonprogressive lesion to an immature brain, occurring in utero, near the time of delivery or within the first 3 years of life. Although more than 50% of cases of CP have no known etiology, several factors, occurring at different points in time, are thought to be risk factors for future CP.

In the prenatal period, congenital infections (TORCH—Toxoplasmosis, Rubella, Cytomegalovirus, Herpes, and others), often clinically unrecognized in the mother, can cause a spectrum of involvement, from severe microcephaly, seizures and spastic quadriplegia, to mild diplegia. Gestational toxins include iodine that may lead to diplegia and organic mercury intoxication while may lead to quadriplegia. Intrauterine subdural hemorrhage may cause hemiplegia (12). During the perinatal period, complications of prematurity include birth weight under 800 g, Grade III and IV intraventricular hemorrhage, prolonged seizures, and an APGAR score of less than 3 at 20 minutes. In full-term gestations, abruptio placenta, placenta previa, nuchal cord, or meconium aspiration can result in neonatal asphyxia, although recent evidence suggests asphyxia may be secondary to underlying prenatal malformations that also result in CP. Finally, hyperbilirubinemia secondary to Rh disease, G6PD, or ABO incompatibility may result in kernicterus, with deposition of bilirubin in cranial nerve nuclei and basal ganglia resulting in athetoid (dyskinetic) CP.

During the postnatal period, bacterial or viral sepsis or meningitis, especially within the first 6 months, can cause residual motor impairments. Traumatic brain injury can be due to child abuse ("shaken baby" syndrome with subdural hematoma and retinal hemorrhage), fall from heights, and motor vehicle accidents. Near-drowning causes hypoxic ischemic encephalopathy. Stroke syndromes with hemiplegia may be caused by traumatic delivery as well as by cyanotic congenital heart disease (e.g., Tetralogy of Fallot), clotting disorders, and ruptured arteriovenous malformations (13). Heavy metal and organophosphate ingestion can cause quadriplegia.

Clinically, gross motor delay is seen in all such patients, with lack of sitting after 6 months being the most common initially recognized deficit. Poor head control may be recognized earlier in the more involved child while delayed ambulation to after 16 to 18 months is seen in the more mildly involved. Motor delay, however, demonstrates poor diagnostic accuracy since the overwhelming majority of children showing isolated gross motor delay will eventually develop normally.

**FIGURE 56-5.** Opisthotonic posture in a spastic quadriplegic.

Abnormal motor characteristics (quality of movement) are often mistaken for "early" milestones, but represent influences of abnormal tone on the child's movement capabilities; for example, "rolling" at 2 months by opisthotonic posturing (Fig. 56-5), "handedness" at less than 1 year in hemiplegics, "walking" at 4 months by reflex steppage. Additional abnormal movement patterns include w-sitting (Fig. 56-6) and sacral

**FIGURE 56-6.** W-sitting due to hamstring spasticity in a child with spastic diplegia.

sitting with posterior pelvic tilt due to hamstring spasticity, bunny hop crawling, and coming to stand through symmetric extension of the lower limbs due to poor pelvic dissociation in children with diplegia, and buttock hitching in hemiplegics. As the child achieves ambulation, abnormal gait patterns (crouch gait, “jump” stance, etc.) are seen.

Alterations in tone are seen both chronologically and positionally. Early hypotonia, seen universally, gives way to later hypertonia. Hypotonia or normal tone seen when the child is supine gives way to hypertonia when posturally stressed (such as ventral or vertical suspension).

Reflex abnormalities include muscle stretch reflexes as well as primitive reflex abnormalities. Infants, however, tend to be relatively hyperreflexic normally, limiting the usefulness of this finding, unless associated with either asymmetry (suggestive of a hemiplegia) or excessive spread of the reflexogenic zone (seen in severe spasticity). Hypo or areflexia is useful however in the differential diagnosis of infantile hypotonia (early CP vs. neuromuscular disease).

Primitive reflexes are body postures dictated by head position and are seen at birth, become more elicitable in the first 2 to 3 months, and normally start to fade by 4 to 6 months. Their presence after 6 months is deemed abnormal. However, the ability to obtain the reflex on every attempt or the infant's persistence in the reflex posture for more than 30 seconds is considered abnormal at any age. Commonly elicited reflexes include the asymmetric and symmetric tonic neck reflexes, tonic labyrinthine reflex, and moro reflex. Abnormal postures at rest are often manifestations of primitive reflex patterns. Examples include fisting with cortical thumb position, extensor thrusting of the lower limbs with scissoring, and asymmetric tonic neck posturing.

The differential diagnosis of CP includes syndromes of early hypotonia (14) and developmental delay but without marked facial dysmorphisms. Two common examples include the Prader-Willi syndrome of low birth weight, normal neonatal length, hypogonadism, small hands and feet with tapered digits and a deletion of the long arm of chromosome 15 and Sotos syndrome of large birth weight, macrosomia with megencephaly, large hands and feet, prominent forehead, and advanced bone age. The Rett syndrome of normal early development leading to loss of speech by 9 to 18 months, stereotypic hand movements, sighing respirations, and spasticity is seen in females only and is associated with a genetic abnormality on the long arm of the X-chromosome (15).

Metabolic disorders include endocrine (thyroid, infant of diabetic mother), amino acid (PKU), and storage disorders (mucopolysaccharidoses).

Congenital neuromuscular diseases presenting with hypotonia, hypo or areflexia, and delayed motor development can be confused with the early hypotonic phase of CP. Examples include infantile Werdnig-Hoffman disease (WHD), congenital muscular dystrophy (CMD), congenital myotonic dystrophy (CMYD), hereditary motor/sensory neuropathies, etc. These will be discussed in greater depth later in this chapter.

Progressive central nervous system diseases may mimic CP until the appearance of neurologic deterioration. Examples include metachromatic leukodystrophy, olivopontocerebellar degeneration, Friedrich's ataxia, and ataxia telangiectasia. HIV encephalopathy, however, is the most common intrauterine-acquired neurodegenerative disease.

A thorough history for predisposing factors as well as possible neurologic deterioration should be obtained. Physical examination should stress recognition of dysmorphic features (syndromes), muscle weakness, hyporeflexia or hyperreflexia, the presence of abnormal movement patterns, and the abnormal retention of primitive reflex postures.

Laboratory examination should include blood and/or urine screens for amino acids, organic acids, serum lysosomal hydroxylase enzyme battery, thyroid function, and creatine kinase (CK) as indicated. Cultured skin fibroblasts for metabolic assay may be necessary if serum or wbc testing is unrevealing.

If diseases of nerve or muscles are being considered, electrodiagnosis allows differentiation of neuropathy from myopathy from normal with 85% to 90% accuracy for neuropathy but with only 40% accuracy for myopathy. Muscle and/or nerve biopsy as well as DNA analysis may be indicated for confirmation. MRI and cranial ultrasound in the perinatal period demonstrating cystic periventricular leukomalacia as well as ventricular enlargement may be predictive of disabling CP (16,17). CNS imaging studies are also useful in ruling out AVM or tumor in hemiplegia of unclear etiology.

Classification of CP is by tonal type and part of body involved. Spastic CP comprises 70% to 85% of cases with further subdivision based on the topographic distribution of the spasticity. Hemiplegia, diplegia, and quadriplegia account for about 90% of spastic CP's with each contributing equally. Triplegia and monoplegia account for the other 10%.

Hemiplegia may result from focal perinatal injury and has the highest incidence of CT/MRI abnormalities, usually in the distribution of the middle cerebral artery. The most common presentation is failure to use the involved hand, although hitching on the buttocks rather than crawling on hands and knees is also seen. The upper limb is invariably more involved than the lower limb. Sensory deficits are difficult to evaluate in children under 4 years old and are likely underappreciated (18). Ambulation is usually achieved by 2 years unless severe mental retardation is an associated finding. Growth retardation of the affected side and an associated parietal lobe syndrome are seen in 50%. Initial seizures may occur as late as 5 years old. Long-term disability is usually more cosmetic than functional.

Diplegia represents the most common type of CP seen in premature babies. There is disproportionate involvement of the lower limbs, although upper limb abnormalities, manifested as motor perceptual dysfunction, are very common. Most children with diplegia eventually ambulate, although both lower limb orthoses and upper limb devices may be required and distances covered varies.

Triplegia presents with relatively symmetric involvement of the lower limbs and marked asymmetric involvement of the upper limbs.

Quadriplegics, also termed *total body involved* have the highest incidence of significant cognitive disability with 25% severely involved, 50% moderately involved, and 25% mildly involved. Lower limbs are usually more involved than upper limbs with asymmetries not unusual. A brief period of hypotonia giving way to early spasticity is usually a poor prognostic sign for independent mobility.

Dyskinetic (athetoid/dystonic) CP accounts for 5% to 8% of cases. In the past, most cases were associated with kernicterus due to Rh disease. Athetosis, dysarthria, sensorineural deafness, and paralysis of upward gaze were the usual signs, while intelligence was often normal, since cerebral cortex was spared. Today, dyskinetic CP is more commonly seen as part of the picture of diffuse hypoxia and may be associated with spasticity, seizures, and retardation (19). The period of hypotonia is usually longer, from 18 to 36 months, before the abnormal movement disorder appears.

Rarer types include atonic (hypotonic) and ataxic CP. The latter is usually associated with hypotonia. If spasticity is present, progressive CNS diseases such as Friedrich's ataxia must be ruled out.

### Prognosis for Ambulation in CP

"Will my child walk?" is usually the question asked most frequently by parents of a newly diagnosed child with CP. In the discussion that follows, one must clarify not only distances involved (household vs. community) but also the quality of the gait and need for both orthoses and/or upper limb assistive devices. Several clinical factors are relevant. The clinical type of CP is important. All children with hemiplegia will walk as will most with true ataxia, while those with atonia usually will not. Those with quadriplegics, diplegia, and dyskinesia vary. Molnar has shown that if independent sitting occurs by 2 years, prognosis for ambulation is good (20). Badell reported that ability to crawl on hands and knees by 1.5 to 2.5 years was a good prognostic sign (21). Persistence of three or more primitive reflexes at 18 to 24 months is a poor prognostic sign (22). Recently, the ability to transition from supine to prone by 18 months was shown to be a predictor of independent ambulation in spastic diplegics (23). Marginal ambulators during childhood may lose functional ambulation during or after adolescence due to progressive orthopedic deformity, insufficient muscle power and/or capacity to accommodate increased height and weight and social/emotional problems. Combinations of independent ambulation and use of wheeled mobility for greater distances should be introduced. Power mobility as a means of independent function should not be delayed in favor of awaiting walking as children as young as 3 years old can learn to "drive" (24). Parental negative feelings are rapidly replaced by positive ones once independent movement and its effect on the child are observed (25).

### Associated Disabilities

Mental retardation of moderate to severe degree is seen in one third, of mild degree in another one third, with the remaining one third showing normal intelligence. In the latter group, fewer than expected fall into the superior range. Those with pure dyskinesia as a rule are the brightest, while those with atonia and quadriplegia are most involved. Retardation is usually mild in those with diplegia and hemiplegia and may be confused with learning disabilities. Preservation of receptive language skills is a better indicator of good cognitive function than expressive language. Hearing loss should be ruled out prior to making judgments regarding receptive skills. Early educational intervention is a reasonable, if unproven, "treatment" and has been mandated by federal law (Public Law 99-457, 1986).

Seizures are seen in up to 35% to 40% of children with CP (26) and are most common in postnatal CP, and about 60% to 70% of those with hemiplegia and quadriplegia. Seizures are seen in only 25% to 33% of children with dyskinesia and diplegia. Imaging may be considered to rule out structural lesions and EEG characterization is useful. Anticonvulsant management is similar to those with idiopathic epilepsy, although the risk of breakthrough seizures when medications are discontinued after being seizure free for 2 years is higher in hemiplegic CP (approximately 60%) than in non-CP children (40%). Children with diplegia have a lower rate (about 14%) of breakthrough seizures (27).

Abnormal vision is seen in 50% of children with CP. Muscle imbalances cause esotropia, exotropia, or hyperopia and are most frequent in diplegia and quadriplegia. Secondary amblyopia can occur. Homonymous hemianopsia can be seen in hemiplegia. Paralysis of upward gaze is seen in pure dyskinesia. Nystagmus is seen in ataxia. Defective tracking can be seen in all types of CP. Most importantly, the possibility of refractory errors as a cause of poor vision should not be overlooked. This is twice as common in spastic CP as in dyskinesia. Surgical correction of muscle imbalances is mostly cosmetic, while optometric "exercises" are controversial, with little evidence of lasting improvement.

Hearing loss may be conductive due to abnormal Eustachian tube function as a result of palatal distortion or sensorineural due to aminoglycoside treatment during the neonatorum. Early assessment is possible with ABRs, although this modality assesses high frequencies only and is subject to false positives in the first 6 months. Amplification for those with bilateral hearing loss is justified.

Dental problems include malocclusions and enamel dysplasias secondary to palatal distortions and abnormal oromotor reflexes (suckle/swallow, tonic bite, rooting, etc.). Inappropriate administration of tetracycline in the newborn nursery is an avoidable cause of enamel dysplasia. CP children are also at increased risk for caries due to poor handling of secretions and food, as well as due to chronic drooling. This can be a source of pain, leading to increased agitation, worsened spasticity, and greater difficulty in parental handling. The adverse social

implications for the child are obvious. Early dental treatment before 3 years old is therefore vital. Anticholinergic treatment, including scopolamine patches for drooling, holds promise with several studies showing consistent long-term improvement. Potential side effects include constipation, urinary retention, and mood changes, all of which reverse with discontinuing medication. Most recently, Botulinum toxin injection into the parotid glands have been tried with effects lasting up to 4 months reported (28).

Increased risk of respiratory infections is due to both extrinsic (abnormally high tone and poor control over chest muscles leading to poor sigh and cough mechanisms) and intrinsic (bronchopulmonary dysplasia) reasons. Early antibiotic treatment is justified.

Malnutrition is more common in moderately to severely involved children but can also affect the more mildly involved (29). Abnormal oral motor function affects ability to handle food with a resulting increased risk of aspiration. The effect of poor feeding skills on survival to adulthood is profound (30). Disordered GI motility with reflux proximally and poor transit time distally is seen. Video swallow studies with multiple temperatures and textures of food may define abnormal mechanisms, but the question of relevance to every day feeding situations has been raised. For many children, gastrostomy tube placement not only improves nutrition but resolves the tension associated with feeding, thereby improving social emotional conditions.

A “neurogenic” bladder can occur in the face of normal sensation and takes the form of either a disinhibited bladder or a spastic dyssynergic bladder due to external sphincter spasticity coupled with uncontrolled spastic detrusor contraction. Abnormal urodynamic studies have been seen in more than 85% of symptomatic patients. Similarly, spasticity of the external anal sphincter can lead to difficult initiation of bowel evacuation and secondary constipation. Cutaneous stimulation and sacral cleft massage may be useful. Ditropan for the spastic detrusor may also be helpful (31).

Behavior disorders include true emotional lability as part of an organic pseudobulbar palsy consisting of dysarthria, drooling, and poor chewing. Attention deficit disorder with hyperactivity may be seen. Poor peer acceptance leading to a negative self-image, school phobia, depression, and anger may be exacerbated during normal periods of transition; for example, preschool to kindergarten, and early adolescence. The more mildly physically involved child may actually have more social and peer group difficulties than the severely involved child with wheelchair-bound quadriplegia—spastic hand posturing, lurching “effeminate” gait, etc. Limited participation in school results from both physical impairment and cognitive-behavioral abnormalities (32). Psychosocial support including psychotherapy is indicated as soon as a problem is identified.

### Therapy in the Management of CP

The multidisciplinary management of the motor handicap in CP maximizes potential, but does not “cure” brain damage.

“Physical” therapy consists of a hands-on approach by physical, occupational, and speech therapists to improve gross motor, fine motor, and oromotor function. Developed in the early 1960s by the Bobaths, neurodevelopmental therapy (NDT) (33) is the most popular “system” of therapy in use today. It emphasizes hands-on facilitation of movement and positioning to “normalize” tone and reduce the influence of abnormal postures (including primitive reflexes). This can be further assisted by the use of positioning aids, such as sidelyers, adaptive seat inserts, and prone standers.

Conductive education (34), developed at the Peto Institute in Hungary, has received recent support as a system capable of “treating” many children in a non-staff-intensive setting. “Educators” or “conductors” encourage spontaneous achievement of motor activity without regard for abnormal quality of movement. The “end” is more important than the “means.” Additional therapy systems include craniosacral manipulation, hyperbaric oxygen (35), and various electrical stimulation systems, both functional electrical stimulation (FES) (36) and threshold electrical stimulation (TES) (37,38). No system of therapy has been objectively shown to result in a greater degree of improved motor function than that expected with a program of passive range of motion only (39). The role of progressive resistive exercises (PREs) for strengthening has been questioned with the previously concern of worsened spasticity not seen. However, while strength can be increased, the extent of functional improvement is not clear (40).

Bracing goals include reduction of abnormal tone, avoidance of deformity, and facilitation of normal movement patterns. Lightweight plastics are widely used and include aquaplast (low temperature, softer, direct fabrication possible) and polypropylene (high temperature, more rigid, fabricated from cast mold). Where metal components are necessary, lighter weight alloys have replaced steel.

In the lower limbs, inframalleolar and supramalleolar orthoses (SMOs) are used primarily to control foot and talocalcaneal alignment with little direct tibiotalar control (41). Ankle foot orthoses (AFOs) add direct tibiotalar control and indirect control of the knee. Setting the ankle in neutral to slight dorsiflexion promotes heel strike and limits knee recurvatum. Articulated AFOs allow setting of a plantarflexion stop while allowing free dorsiflexion and promote active use of anterior tibialis as well as passive dorsiflexion necessary in stair climbing, crouching, and half-kneeling. The addition of twistors (either rod or elastic) attached to a pelvic belt, adds an element of control over hip internal or external rotation. Floor reaction AFOs, with the ankle set at neutral dorsiflexion and molded anteriorly to just below the patella limit crouch gait secondary to hamstring spasticity. Posterior leaf spring orthoses (PLSAFOs) are solid ankle orthoses, thinned posteriorly to simulate push-off at the end of stance phase, following passive dorsiflexion in early to midstance. Knee-ankle-foot orthoses (KAFOs) add direct control over knee flexion and extension as well as varus and valgus, but add bulk and weight. Similarly, hip-knee-ankle-foot orthoses (HKAFOs) add control over hip

position. Neither of the latter two braces significantly improves gait capability, but they do prevent deformity and may facilitate standing. Use of ratchet joints may allow for gradual reduction of flexion contractures over lengthy time periods.

The primary purpose of upper limb orthoses is to prevent fixed deformity. Minimal improvement in hand function is seen with use of upper limb orthotics. The cortical thumb loop orthosis, a simple fabric loop providing pressure into the thenar eminence, promotes abduction and extension of the thumb and facilitates thumb-opposed grasp. Wrist and/or elbow extension splints can be used during the day to extend reach, or at night to prevent flexion deformities. More recently, restrictive casts and slings have been used on the functional upper limbs of children with hemiplegia in constraint-induced therapy or “forced use” programs with early encouraging results (42,43).

### Medications for Spasticity

By limiting the effects of spasticity, deformity can be prevented, nursing care improved, bracing better tolerated, and function enhanced. Most commonly used medications include Baclofen (Lioresal), Diazepam (Valium), Dantrolene Sodium (Dantrium), Clonidine and Zanaflex (Tizanidine).

Baclofen acts at GABA-B receptors in the spinal cord. Dosage starts at 2.5 to 5 mg bid, increasing 2.5 mg per dose every 3 days. Effects can be expected by 1 mg/kg/day, although doses as high as 2 mg/kg/day may be well tolerated. Side effects include confusion, depression, weakness, GI upset, and lowered seizure threshold.

Diazepam acts at both the brainstem reticular activating system and the spinal cord. Dosage starts at 1 to 2 mg bid and is titrated up to the desired effect. Side effects of lethargy, urinary retention, and dependence may limit usefulness. Prompt withdrawal may cause seizures. Dantrium acts at the level of intra- and extrafusal muscle fibers resulting in decreased release of calcium from sarcoplasmic reticulum. Dosage starts at 0.5 mg/kg/day. Weakness, fatigue, lethargy, and diarrhea are potential side effects. Liver function tests and blood counts are monitored during use.

Clonidine, an  $\alpha$ -agonist originally used to treat hypertension in autonomic dysreflexia, was found serendipitously to reduce spasticity. Dosage starts at 0.05 to 0.1 mg bid, increasing as needed. Side effects include temporary sedation as well as hypotension. Delivery by transdermal patches in 0.1, 0.2, or 0.3 mg doses, each lasting 7 days, adds a measure of convenience. More recently, Zanaflex starting with 1 to 2 mg/day, has replaced oral Clonidine.

While medications have been shown to be capable of reducing tone, the doses required may cause significant side effects (most commonly sedative or GI) so as to limit the amount of functional improvement realized.

### Intrathecal Baclofen (ITB) Infusion

Intrathecal infusion of Baclofen offers the advantage of bypassing the poor ability of Baclofen to cross the blood-brain barrier, leading to CSF concentrations 30 times higher than

when given by mouth. The incidence of side effects is also reduced. The intrathecal catheter is inserted by lumbar puncture and positioned at the T10 spinal level. The dose is delivered by a programmable pump implanted in a subcutaneous abdominal pouch and varies from 30 to 800  $\mu$ g/day. Changes in dose as well as mode of delivery (continuous infusion, bolus, or variable rate) can be made by transcutaneous telemetry. While tone reduction is most significant in the lower limbs, effects on the upper limbs and trunk are also seen by upward migration of infused Baclofen. Functional changes in gait and upper limb use can be seen (44). Potential complications are multiple and include CSF seroma, leaks, catheter kinking or dislodgement, infection, and pump failure. However, the rate for any single complication is quite low (45–47). Battery life is currently up to 7 years, but replacement requires a surgical procedure. The cost of the pump and its placement is about \$25,000, with refills every 2 to 3 months costing about \$750.

### Injection Therapy in the Management of Spasticity

Previously used in various movement disorders (Blepharospasm, Spasmodic Torticollis, Spasmodic Dysphonia), Botulinum Neurotoxin Type A (Btx-A) has recently been used in the treatment of spasticity in children. Btx-A acts by irreversibly blocking presynaptic release of acetylcholine (ACh) at neuromuscular junctions (NMJs). Given as an IM injection, the onset of the clinical effect is delayed by 24 to 72 hours due to a complex process of neuronal uptake by endocytosis and subsequent binding to presynaptic receptor sites in the axon terminal. The toxin blocks binding and fusion of vesicles with the presynaptic membrane and interrupts ACh release. Clinical effects peak at 2 to 6 weeks and last about 3 to 6 months with reinnervation by terminal axon sprouting. Large muscles may require several injection sites. Common clinical practice allows injection of 12 to 14 U/kg divided among all injected muscles.

Advantages over nerve block include no need for anesthesia, no sensory side effects, and no apparent tolerance to repeated injections. Loss of effect due to the development of antibodies to Btx-A has been rarely described in adults receiving higher doses (>400 U) every 2 to 3 months. In one study of 27 patients, Btx-A significantly improved positioning in children with severe quadriplegia, including those with paraspinal spasticity (48), as well as improving gait function in those with hemiplegia and diplegia with severe gastrocnemius spasticity (49). In another recent study, Btx injected into thenar muscles reduced the CP cortical thumb and resulted in significant hand opening. Injection of biceps and forearm flexors reduces “flexion synergy” pattern in children with hemiplegia, but verification of functional improvement is still forthcoming. Typical injection patterns and suggested doses for individual muscles are available (50,51).

Local injections of phenol or alcohol near a peripheral nerve or muscle motor point cause chemical neurolysis resulting in temporary decrease in tone and strength of the affected muscle. Distal regeneration from the site of injection results in loss of effect after 4 to 6 months (less for motor point blocks

than for nerve blocks). Potential benefits include prevention of deformity and improved function through facilitation of other therapies—such as physical therapy and tolerance of orthoses or positioning devices. In younger children, these blocks may buy time before requiring surgical intervention. Potential negative effects include temporary sensory dysesthesias (nerve blocks only), especially in the tibial nerve and upper limb nerves as well as permanent weakness leading to deformity (e.g., tibial nerve block may lead to calcaneovalgus foot).

In the lower limbs, obturator nerve blocks (anterior and posterior branches) reduce adductor tone, diminish scissored gait, and promote passive abduction as a means of protecting hip joint integrity. Sciatic branch blocks to the medial hamstring muscles (semimembranosus and semitendinosus) lessen crouch gait and internal rotation postures (52). Tibial nerve blocks (and more recently, tibial branch blocks to the heads of the gastrocnemius) diminish plantarflexion tone and allow better tolerance of AFOs. Femoral nerve blocks diminish spastic genu recurvatum. In the upper limbs, musculocutaneous nerve blocks promote elbow extension and facilitate reach. Median and ulnar nerve blocks are generally avoided due to the high risk of sensory dysesthesias. Motor point injections into the forearm, wrist, and finger flexors are preferred. Except for obturator block, Btx-A is the preferred agent of choice for affecting spasticity in the muscles supplied by the above nerves.

### Surgery in CP

Orthopedic surgical intervention can be classified as either soft tissue or bony. Soft-tissue procedures are done at the muscle or tendon level and consist of releases, lengthening, or transfers. Recurrence of abnormalities tends to occur with the former two, especially if done before 4 years old (53). Transfers also tend to weaken the muscle at its new position but may balance forces across a joint, for example, medial hamstring transfer leading to less knee flexion, split posterior tibialis transfer leading to less ankle inversion, and rectus femoris transfer to sartorius transfers leading to less knee recurvatum (usually done in conjunction with hamstring lengthening). Bony procedures consist of either joint fusions (ankle or spine), (de)-rotations (of the femur or tibia), or angulations (of the femur). A list of specific procedures is presented below (Table 56-5). The current trend is for multilevel soft-tissue surgery (rectus transfer, hamstring lengthening, and tendoachilles lengthening, TAL) and bilateral bony surgery (bilateral femoral varus osteotomies) to avoid imbalances and asymmetries. Computerized gait analysis measuring joint kinematics, kinetics, and dynamic EMG is recommended by many prior to undertaking complex orthopedic surgery (54,55).

Intensive postop rehabilitation is required to maximize gains and can be started while the child is still casted. Activities include upper limb strengthening, use of a tilt table to decrease postural hypotension and increase trunk control, and wheelchair and scoliosis cart ambulation to maintain cardiovascular conditioning. Once casts are removed, aggressive passive and active assistive range of motion, lower limb strengthening,

**TABLE 56.5 Orthopedic Surgical Procedure by Joint**

Foot and ankle
TAL—for ankle equinus
SPLATT (split anterior tibialis transfer)—for inversion and dorsiflexion
Split posterior tibialis transfer—for inversion and plantarflexion
subtalar arthrodesis—for calcaneovalgus. Often combined with lateral column (fifth metatarsal ray) lengthening
Knee
Hamstring lengthenings—for crouch, internal rotated gait
Rectus transfer (to sartorius or semitendinosus)—to balance hamstring weakness and prevent recurvatum
TIBIAL derotation osteotomy—for internal rotation
Hip
Psoas lengthening (intramuscular over the pelvic brim) for hip flexion
Adductor tenotomy—for scissored gait or early hip subluxation
Varus derotational osteotomy (VDO)—for hip subluxation
Pelvic shelf procedures (Salter, Chiari, etc.)—for subluxation with severe acetabular dysplasia

transfer training, and gait training are begun. Generally, for complex procedures, up to 6 months may be required before the child's preoperative functional status is regained, with further progress made for up to another year.

Selective posterior (or dorsal) rhizotomy (SPR, SDR) involves sectioning a variable percentage of sensory nerve rootlets after L2-S1 laminectomy. Theoretically, this results in a decrease in peripheral excitatory influences on the anterior horn cell in a spastic patient. Favorable patient selection criteria include lack of dystonia and/or athetosis, preservation of functional strength independent of spasticity, presence of selective motor control, younger age (3 to 8 years), lack of significant joint contracture and few previous orthopedic procedures. In addition, cognitive preservation, motivation, and positive family supports are important. Selection of "abnormal" rootlets is based on electrophysiologic measures (sustained contraction after a 1-second stimulation train, and spatial spread of contraction to different spinal root level muscles) and clinical (briskness and overflow of contraction) criteria at the time of surgery. It is preferable not to section all rootlets at any given level. More recent studies suggest contralateral spread of the EMG response or spread to the upper body may be the most valid abnormal criteria (56). Postop therapy early on avoids excessive hip flexion (>70 degrees), straight leg raising (>30 degrees) or trunk rotation, and passive flexion or extension is avoided in order to avoid stress on the operative site. By 6 weeks postop, full PROM can be started as well as functional strengthening and mobility training with or without orthoses. Small but statistically significant improvements in gait function as measured by the GMFM have been documented 1 year postop (57). Additional improvement in gait function has been documented for up to 2 years postop, but may not be significant when compared to physical therapy alone (58).

Negative effects of SPR include hypotonia (usually transitory immediately postop, but occasionally lasting up to 6 months), weakness (unmasked by reduction of tone), sensory changes and bladder dysfunction (both usually of brief duration), hip dislocation (though exacerbated by sparing of L1 root leading to unbalance hip flexor spasticity) (59), and spinal deformity (no significant evidence of scoliosis is reported but lordosis may be associated with sparing of L1) (60). Some centers now start SPR at the L1 level.

There are recent reports of decreased plantar flexor spasticity as a result of sectioning rootlets at the S2 level. In one study, performing a “pudendal neurogram” (SSEP technique), and not sectioning rootlets carrying pudendal nerve responses, reduced bladder dysfunction from 24% to 0% (61). Results of SPR have been mixed and there is still great controversy regarding advantages of SPR over orthopedic surgery. Additional unanswered questions regarding SPR include the need for EMG monitoring during surgery (62) as well as the role of limited SPR, either by level (only L4 through S1) or percentage of rootlets cut (only 25% to 35%).

## Progressive Neuromuscular Disease

### Early Diagnostic Features and Differential Diagnosis

With the site of pathology within the motor unit, these disorders can be classified as originating from the anterior horn cell, peripheral nerve (either myelin or axonal), NMJ or muscle.

### Approach to Diagnosis

In the history and physical examination, one should look for evidence of hypotonia with weakness, disproportionately delayed motor milestones compared to other developmental areas, and hyporeflexia or areflexia. Serum CK is a useful laboratory test for possible primary muscle disease, although consistent elevations are seen in dystrophinopathies and inflammatory muscle disease only. Serum electrolytes (particularly potassium), organic acids (lactate, pyruvate), and amino acids (carnitine) may also be useful. Genetic testing (high-resolution banding and DNA analysis) has allowed diagnosis of many diseases based on abnormal genetic loci (Table 56-6) and may avoid the need for biopsy as well as allow for prenatal diagnosis. Electrodiagnostic studies give about 90% positive correlation with neuropathy but only 44% with myopathy. Biopsy of either muscle or nerve, performed as open procedures, confirms diagnosis of nerve or muscle disorders. H&E stain of muscle shows gross structure—size of cells, uniformity, fatty or fibrous proliferation—while histochemical studies divide cells into subpopulations of type I (light) and type II (dark) cells (ATPase), show abnormal intracellular organelles (NADH-Trichrome) or accumulations of storage material (PAS). Electron microscopy gives additional resolution. Fluorescent antibody staining techniques can be used for dystrophin analysis in the dystrophies. Nerve biopsy assesses involvement of large versus small fibers and myelinated vs unmyelinated fibers.

**TABLE 56.6 Genetic Loci of Select Neuromuscular Diseases**

Locus	Disorder
1q21.2q23	Charcot-Marie Tooth, type 1B
1q21q23	Nemaline myopathy, autosomal dominant
4q35	Facioscapulohumeral muscular dystrophy
5q13	Werdnig-Hoffman (infantile) SMA
5q13	Kugelberg-Welander (juvenile) SMA
15q	Limb-girdle muscular dystrophy
17p13.1	Charcot-Marie Tooth, type 1A
17q13.1q13.5	Paramyotonia congenita
19q13.3	Myotonic muscular dystrophy
19q12q13.2	Malignant hyperthermia syndrome
19q13.1	Central core disease
Xp21.2	Duchenne muscular dystrophy
Xp21.2	Becker muscular dystrophy
Xq13	Charcot-Marie Tooth, X-linked
Xq28	Emery-Dreifuss muscular dystrophy
Xq28	Myotubular (centronuclear) myopathy
Mitochondrial	MERRF—myoclonic seizure, ragged red fibers
	MELAS—encephalomyopathy, lactic acidosis, stroke
	Cytochrome c oxidase deficiency—benign infantile myopathy fatal infantile myopathy

## Specific Disease of Infants and Toddlers—The “Floppy Baby”

While the overwhelming majority of “floppy babies” will eventually show normal motor development (63), non-neuromuscular causes of pathologic hypotonia should also be considered (64). In early CP, clues in the history (prematurity, asphyxia, etc.) and physical exam (superimposed hypertonicity, hyperreflexia, abnormal primitive reflex profile) should arouse suspicion. One disease to consider is the Prader-Willi syndrome of hypotonia, small for gestational age, typical facies, failure to thrive early replaced by hyperphagia and marked obesity after 3 to 4 years, hypogonadism, small hands and feet, tapered digits, and a deletion at the long arm of chromosome 15-15q-. At the opposite end of the spectrum is Sotos syndrome or cerebral gigantism. Characteristics include hypotonia with macrosomia, megencephaly, large hands and feet, typical facies. Both syndromes are easily confused with congenital myopathies due to the hypotonia without obviously marked facial dysmorphisms. CNS infections including bacterial and viral meningitis and sepsis as well as botulism cause acute presentations of hypotonia in a child who appears toxic.

## Anterior Horn Cell Diseases

Spinal muscle atrophy (SMA) presents in two forms during infancy. Infantile SMA I or WHD is seen in 1/15,000 to 25,000 live births. Transmission is via an autosomal recessive inheritance pattern. The onset of hypotonia (Fig. 56-7) and global weakness with facial muscle sparing within the first weeks of life is

**FIGURE 56-7.** Global hypotonia in SMA I.

typical. Fasciculations are seen in the tongue only and there are no joint contractures. Stretch reflexes are absent but sensation is normal as is the serum CK. Electrodiagnosis reveals normal motor conduction velocities but markedly decreased compound muscle action potential (CMAP) amplitudes. Sensory latencies and amplitudes are normal. EMG may demonstrate “chronic neuropathic” changes, although fibrillations may also be seen. Muscle biopsy shows rounded fibers, with areas of atrophy and compensatory hypertrophy. DNA analysis reveals a deletion on the long arm of the fifth chromosome (5q13) near the area of the survival motor neuron (SMN) gene (65). DNA testing is 95% reliable for diagnosis and can also be used for prenatal testing. The clinical course is progressively downhill to death in 90% by 2 years although long-term survival is now possible with the use of home ventilator support (66,67). Rehabilitative efforts should focus on provision of appropriately supportive

adaptive seating and assistive technology for mobility and activities of daily living (ADLs).

Intermediate SMA II (also called *chronic Werdnig-Hoffman disease*) has the onset of progressive weakness and areflexia later in infancy, usually after sitting is achieved. A few patients become limited household ambulators during childhood with the assistance of AFOs and walkers. Fasciculations are more common and minipolymyoclonus is seen. Serum CK levels may be up to five times normal and increase with age. In addition to the nerve conduction abnormalities seen in type I SMA, large-amplitude motor units are more frequent on needle EMG. A tremulous baseline in the EKG represents cardiac muscle fasciculations and is almost pathognomonic for this disease. Muscle biopsy shows angular fibers and type grouping. Genetic findings are similar to SMA I. The clinical course is one of gradual progression with long-term complications of chronic wheelchair use (scoliosis, contractures, respiratory insufficiency) typically leading to death in early adulthood (Fig. 56-8). Contracture prevention, early spinal bracing, and surgical correction of scoliosis are necessary to allow optimum respiratory status to be maintained. As weakness progresses, noninvasive assisted ventilation may prolong life.

Diseases at the level of the NMJ include transient neonatal myasthenia gravis (MG) and congenital myasthenic syndromes. The former is seen in newborns of mothers with autoimmune MG due to transplacental transmission of AntiChR antibodies. The onset is usually within the first 24 hours after birth with feeding disorders, hypotonia, respiratory distress, weak cry, and facial weakness seen in decreasing order of frequency from over 90% to 50%. Ptosis is seen in only 15% of cases. Diagnosis is by either tensilon test or electrodiagnosis (see the text on autoimmune MG later). Symptoms are self-limiting and nonrecurring. Treatment is primarily supportive, although anticholinesterase (AChE) drugs (Mestinon) may be required in severe cases. Congenital myasthenic syndromes are an as-yet poorly delineated group of NMJ disorders that usually present at birth, but possibly not until years later. Most are autosomal recessive, but sites of pathology within the NMJ can be variably presynaptic, postsynaptic, or both. Diagnosis requires sophisticated electrodiagnostic and biopsy techniques and is available in few specialized centers only.

Peripheral nerve disorders include the hereditary motor-sensory neuropathies (HMSN) that are much more commonly observed in older children and will be discussed later.

**FIGURE 56-8.** Progression of scoliosis (A) after 1 year (B) in SMA II.

### Congenital Myopathies of Infancy

CMyD is an autosomal dominant disorder transmitted from an affected mother. Typical features include severe hypotonia at birth with respiratory distress often requiring prolonged ventilator support (68). Facial diplegia with a characteristic triangular-shaped mouth (Fig. 56-9), equinovarus contractures, and mental retardation are also seen. Clinical myotonia may not appear until 3 to 4 years age, while electrical myotonia is rarely seen at birth and may be absent until 2 to 3 years old. Clinical diagnosis is confirmed by examining the mother who invariably has the adult form of the disease. An abnormal

**FIGURE 56-9.** Typical facies of CMyD.

genetic locus on the long arm of chromosome 19 (19q13.3) results in a trinucleotide repeating sequence (CTG) (69). The number of repetitions, normally between 5 and 35, may be as high as 2,000 and is directly correlated with severity of disease, including cardiomyopathy (70). The genetic and clinical abnormalities tend to increase in severity with successive generations (termed genetic *anticipation*). Muscle biopsy is now rarely required. The clinical course is one of gradual improvement with hypotonia no longer clinically significant by 4 years. All will eventually become at least household ambulators, although soft-tissue surgeries and bracing may be required. Mild to moderate mental retardation, exacerbated by oromotor immobility affecting expressive language skills more than receptive skills, requires special education placement. Multisystem disease consisting of frontal baldness, cataracts, testicular atrophy in males, smooth muscle and cardiac muscle dysfunction, all typical of the adult form of myotonic dystrophy, is seen in

**FIGURE 56-10.** Head lag in CMD.

CMyD adults and leads to a typically shortened life span, with death most commonly due to cardiac dysrhythmias.

CMD, a disorder of variable severity, is transmitted in an autosomal recessive pattern. Severe forms present early with hypotonia, proximal weakness with head and neck muscles involved early (Fig. 56-10), and congenital contractures usually seen distally only (ankles, wrists—"arthrogrypotic"). Cognition is usually normal. Milder forms may present with less severe gross motor delays and weak gait. CK is variably increased, while electrodiagnosis may or may not show "myopathic" patterns. Biopsy is similar to Duchenne dystrophy with variation in fiber size, fiber splitting, central nuclei, and fibrous proliferation. Severity of biopsy abnormalities is not necessarily correlated with clinical abnormalities. The clinical course can be static or slowly progressive, with scoliosis a common complication. Fukuyama CMD, a more severe form of CMD associated with seizures, mental retardation, and abnormal CNS imaging (71), is seen primarily but not exclusively in the Japanese population. With the discovery of the dystrophin-glycoprotein complex, specific component deficiencies have been associated with different forms of congenital dystrophy, the most common being merosin (or laminin) deficiency, which may also be associated with a peripheral neuropathy (72).

Other myopathies, once considered questionably distinct clinical entities, are named after histological changes seen in biopsy specimens treated with special staining techniques. Examples include nemaline (rod-body) myopathy, central core disease, centronuclear (myotubular) myopathy, and fiber type disproportion (73). In addition, each can demonstrate a broad spectrum of involvement (74). Recent discovery of abnormal genetic loci (see table) for many of these histologic myopathies supports the concept that these may indeed be true entities.

## DISEASE OF OLDER CHILDREN

In older children, *SMA III* (*Kugelberg-Welander disease*) presents with proximal weakness during early childhood to young adulthood. Ambulation may be maintained into later years. Calf hypertrophy is seen in 25%, fasciculations in 75%. CK may be elevated two to five times normal. EMG shows a chronic neuropathic pattern (minimal fibrillations and positive sharp waves with large-amplitude polyphasic motor unit action potentials and diminished recruitment). Biopsy can show a mixed neuropathic/myopathic picture or can be nonspecific in 30%. The abnormal genetic locus on the long arm of chromosome 5 (5q13) is seen.

Several HMSN exist and have been classified by Dyck and Lambert. Most common are HMSN I (Charcot-Marie-Tooth—CMT) and HMSN II (neuronal CMT). HMSN III (Dejerine-Sottas) presents in early infancy, involves sensory nerves more often than in other types, and has more palpable nerve hypertrophy. Type IV (Refsum's diseases) is associated with hearing loss and deficiencies in phytanic acid. Type V (familial spastic paraplegia) may have upper motor neuron findings (75). Clinical findings in types I and II are similar.

**FIGURE 56-11.** Coxa valga (A) and mild hip subluxation (B) in Charcot-Marie Tooth.

Foot problems (pes cavus, claw toes, intrinsic atrophy) are common but can be clinically insignificant. In young children, pes planus is the most common presentation. Leg atrophy occurs later. The cavus foot appearance is secondary to progressive denervation leading to atrophy, fibrosis, and contracture in a distal to proximal direction. Type I can be distinguished from type II by electrodiagnosis. Type I gives a demyelinating picture—markedly slowed NCVs with few needle EMG abnormalities, while type II gives an axonal picture—relatively normal NCVs with a more abnormal needle EMG (76) and nerve biopsy. Several abnormal genetic loci have been found—the long arm of chromosome 1 (1q), long arm of chromosome 17 (17q), and an X-linked form. Orthopedic complications include hip dysplasia in about 6% to 8%, often asymptomatic (Fig. 56-11), and neuromuscular scoliosis in about 10%. Progressive cavus deformities and scoliosis may lead to the need for orthoses to improve ambulation and slow progression of spinal deformity. Resistant deformities may require surgical intervention (foot reconstructions, spinal fusions). As near normal physical activity as possible should be allowed.

*Autoimmune* MG occurs with a prevalence of 5 to 10/100,000 population and is four times as frequent in females. Clinically, abnormal fatigue occurs after activity and improves with rest. The onset is usually insidious although it may present precipitously after a febrile illness, allergic reaction, or emotional upset. The most common presenting sign is ptosis (ocular MG) that increases with reading and is accompanied by compensatory forehead wrinkling. Facial weakness may also be seen, presenting as a slack jaw, slurred speech or difficulty swallowing, and limb weakness, proximal more than distal with a positive Gower sign and Trendelenburg gait. Tensilon, a short-acting AChE, given intravenously, reverses weakness within 30 to 60 seconds and lasts 5 to 10 minutes. Electrodiagnostic testing reveals a decrement of more than 10% on 2 to 3 Hz stimulation, while single-fiber EMG (SFEMG) shows abnormal jitter but is difficult to perform in children. Finally, antibodies to ACh receptors (Anti-AChR Abs) can be measured and are elevated in 85% to 90% of patients with generalized

MG, but only 50% in ocular MG. Treatment is based on either improving NMJ transmission with AChEs or decreasing the lytic effect of Anti-AChR Abs by steroids, immunosuppressive therapy, or thymectomy. Commonly used AChEs include Prostigmine (neostigmine) or Mestinon (pyridostigmine). Steroids may be given in high doses once daily, low doses every other day or pulsed, each method having its proponents. Immunosuppression can be achieved by drugs (azathioprine, cyclosporin) IV gammaglobulin or plasma exchange (during crisis). The role of thymectomy is still controversial with optimal response seen when surgery is done within 5 years of onset and in relatively mild cases. Paradoxically though, thymectomy is usually performed only after other treatments have failed.

The presentation of *fascioscapulohumeral muscular dystrophy* (FSHD) is often in adolescent or early adult years. Facial weakness often precedes shoulder girdle weakness. In later years, there may be progression to abdominal and pelvic girdle muscles. Associated abnormalities include high- (and rarely low-) frequency hearing loss and retinal abnormalities (telangiectasia, microaneurysms) in up to 75%. There are no cardiac abnormalities and cognition is preserved. CK elevation and muscle biopsy changes may be minimal. An abnormal genetic locus has been found at the 4q35 site. FSH and *limb girdle dystrophy* have many overlapping features; prominent facial involvement and autosomal dominant transmission favor FSH; proximal weakness and autosomal recessive transmission favor limb girdle. Both show variable severity and in their extremes, can be like Duchenne dystrophy with scoliosis, respiratory disease, and early death. The abnormal genetic locus is on chromosome 15.

*Duchenne muscular dystrophy* (DMD), a sex-linked recessive disorder, is seen in 1 to 3/10,000 male births. Gait deviations present after 2 years of age eventually lead to a Trendelenburg gait, pathognomonic of gluteus medius weakness. Patients come to stand through the Gower maneuver, pathognomonic of proximal pelvic girdle weakness. Gradually, a characteristic posture of tight heelcords, calf pseudohypertrophy (deltoid pseudohypertrophy also common but less visually obvious), a widely abducted stance, and hyperlordosis develops. Dull mentation is seen in about one third. CK is markedly elevated, maximally in the preclinical stage, with values greater than 10,000 not unusual. Values decrease with age as muscle loss progresses, but never approach normal. A “myopathic” EMG (BSAPs, early recruitment) is seen. EKG shows cardiomyopathy with tall R-waves in the right precordial leads and deep Q-waves in the limb and precordial leads. These abnormalities are seen in 70% to 90% of patients and cardiomyopathy causes death in about 10% (77). Biopsy shows variation in fiber size, fiber splitting, central nuclei, fibrous/fatty replacement, and absence of type 2B fibers.

The abnormal genetic locus is at the Xp21 site, resulting in deficient or abnormal muscle protein, Dystrophin, assayed by immunofluorescent techniques in muscle biopsy specimens. Quantification of dystrophin now allows classification of the dystrophies based on the level of dystrophin deficiency. Less than 3% is characteristic of Duchenne while between 3% and 10% suggests severe Becker muscular dystrophy

(BMD) and 10% to 20% suggests mild-to-moderate BMD. Levels above 20% suggest non-Becker/Duchenne dystrophies. Detailed DNA analysis on blood will soon be available using DNA probes, as will prenatal diagnosis with accuracy approaching 95%. Therapeutically, ongoing drug trials continue. Currently, both prednisone as well as androgenic steroids are used (78).

The clinical course is variable but inexorably downhill with ambulation typically lost by 8 to 12 years of age. Ambulation can be prolonged by bracing and/or timely surgical intervention to release contractures (79). Specifically, resection of the iliotibial band, TAL with or without posterior tibialis lengthening or release can prolong ambulation an average of 2 years if done prior to initial entry into the wheelchair. Success depends on having a cognitively preserved patient, motivated for ambulation with a supportive family. Early remobilization is vital and only minimal orthotic support is needed. The wheelchair phase is characterized by progressive weakness, scoliosis in 80% (although 15% of these will not show significant progression and do not require surgical correction), and death by late teens to early twenties, usually secondary to respiratory failure on the basis of restrictive lung disease. Prolongation of useful life is possible by early surgical correction of scoliosis suggested once the curve exceeds 20 degrees and before lung vital capacity becomes less than 20%, and appropriate portable ventilator support (Fig. 56-12).

*BMD* occurs with an incidence only one tenth that of Duchenne. All clinical findings are the same as in Duchenne. Dystrophin deficiency is only partial (between 3% and 20%), rather than complete (<3%) as in Duchenne. The clinical course is protracted compared to Duchenne, with ambulation maintained into the 20s and survival to the 40s. Each form of dystrophy is genetically distinct.

## CONGENITAL BRACHIAL PLEXUS PALSIES

The reported incidence of congenital brachial plexus injuries is 0.6 to 2.6/1,000 live births. The mechanism of injury is traction to the brachial plexus. Most frequent is a neuropraxic injury from which more than 90% will recover fully. Axonal damage, rupture of the nerve, or nerve root avulsions result in variable residual damage. Risk factors include primiparous mothers, prolonged labor, birthweight more than 8.5 lb, shoulder dystocia (present in >50%), traumatic delivery with mid to high forceps, and breech presentation.

Injuries are divided and classified anatomically (80). Erb's palsy involving the upper plexus (C5-7) accounts for about 80% of injuries. Klumpke's palsy involving the lower plexus (C7, C8, T1) exclusively is now felt to be quite rare, with total plexus injuries accounting for 15%. Bilateral plexus injuries are also quite rare. Associated injuries secondary to use of forceps include facial palsies, cephalohematomas, and torticollis. Fractures of the clavicle, humerus and in worst cases, cervical spine can occur as can diaphragmatic paralysis. Horner's

**FIGURE 56-12.** Adolescent with Duchenne dystrophy and early fusion for scoliosis.

syndrome (ptosis, miosis, anhydrosis) can be seen with lower plexus injuries and is secondary to stellate ganglion injury.

On initial examination, the position of the arm is related to muscle imbalances around the pivots (81). Erb's palsies present with the typical "waiter's tip" posture of shoulder internal rotation and adduction, elbow extension and pronation, wrist flexion and thumb in palm (due to loss of extensor pollicis) (Fig. 56-13). Klumpke's posture is the reverse, with shoulder external rotation (abduction usually not seen due to gravity), elbow flexion and supination, wrist extension, and the intrinsic minus hand deformity due to loss of C8, T1 muscles

**FIGURE 56-13.** “Waiter’s tip” posture in Erb’s palsy (upper plexus injury).

(Fig. 56-14). Muscle stretch reflexes are often lost. Sensory deficits, often present, may be difficult to test for in newborns. MRI has shown pseudomeningoceles in both severe and mildly involved patients and may be unreliable. Early electrodiagnostic testing may distinguish neuropraxia from axonal injury and hence may define severity. Most ominous is the preservation of sensory potentials in the face of clinically absent sensation, suggesting root avulsion. The appearance of small polyphasic potentials, so-called nascent potentials may be an early sign of recovery (82).

Treatment in the first week must take into account the presence of a traumatic neuritis (83). Gentle range of motion should be done as well as pinning the end of a long sleeve shirt to the diaper waist to avoid stretching of the shoulder capsule. Later, more aggressive range of motion should include shoulder (87) abduction with scapular stabilization to stretch scapulohumeral adhesions, elbow supination as well as extension, and thumb abduction. Splinting of tight pivots may be considered as may FES to flaccid muscles. Developmental handling encourages activity and provides functional strengthening. Prone propping and wheelbarrel walking strengthen the shoulder girdle, while eliciting righting reactions can

**FIGURE 56-14.** Typical posture of the hand in Klumpke’s palsy (lower plexus injury).

strengthen deltoid, triceps, and wrist extensors. Active reaching in all directions is encouraged. Complete recovery occurs in more than 65% of children, while mild and moderate deficits are seen in 10% each. About 15% will have severe residual deficits. Poor grade elbow flexion with 0 to trace strength in wrist and finger extensors at 6 months old may be predictive of a poor outcome (84).

Since the mid-1990s, early neurosurgical repair of the injured brachial plexus has been advocated by some (85,86). Candidates for surgery have 0 to 1/5 strength in the biceps at 3 to 4 months or have plateaued at 2/5 for 4 months. The optimum age for surgery is less than 9 months since nerve growth factor is at a maximum before 1 year of age, and there is less nerve scarring and distal muscle atrophy at that age. Procedures performed include surgical neurolysis of scars, end-to-end anastomosis with microsurgical fascicular repair, and cable graft of nerve rupture. Intraoperative SSEPs may identify root avulsions not amenable to repair, while motor responses may distinguish neuropraxia from axonotmesis or neurotmesis. Postoperatively, up to 12 months may be needed for return of function to be seen. In one study, all muscles improved at least one grade by 9 months, with average strength in biceps and deltoids reaching 3/5. Surgical neurolysis also resulted in at least one grade improvement, while those patients requiring nerve graft showed the most dramatic improvement of between 2 and 3 grades. Others have questioned the criteria for early surgical repair, with recovery starting as late as 1 year seen (87). Additionally, soft-tissue procedures may be helpful (88). Subscapularis release improves passive shoulder external rotation, especially if performed before 4 years of age. Latissimus dorsi transfers can improve either elbow flexion or extension while shoulder abduction can be improved if coupled with trapezius transfer. Late deficits are largely cosmetic, with the presence of a high-riding, hypoplastic scapula with

winging and loss of scapulohumeral rhythm. An elbow flexion contracture due to radial head subluxation and biceps contracture is almost always seen, and there is frequent shortening of the humeral segment. Finally, as with any disfiguring injury, the adverse effect on psychosocial development should not be underestimated, and appropriate counseling services provided.

## CHILDHOOD TORTICOLLIS

The incidence of congenital muscular torticollis is about 4/1,000 live births, with 75% involving the right side (related to left occiput anterior presentation) (89). More recent studies have shown more equal presentation of right- and left-sided signs. A nontender, soft enlargement in the sternocleidomastoid (SCM) muscle, the so-called olive sign, may be seen within the first 6 weeks (90). It is mobile within the belly of the muscles, gradually decreases in size, and is usually gone within 4 to 6 months. Between 10% and 20% develop persistent torticollis and an additional 25% have mild SCM asymmetry. Secondary deformities including flattening of the ipsilateral face, contralateral occipital flattening, and orbital asymmetry can be seen (91). Ipsilateral hip dysplasia is seen in up to 12%. Typically, there are no spinal abnormalities or neurologic deficits. The differential diagnosis is quite extensive and is outlined in Table 56-7 (92).

The treatment of torticollis should be based first on correcting identified etiologic factors. Conservative therapy should include stretching of the tight neck muscles as well as functional strengthening of contralateral neck muscles by use of lateral and anterior head righting reactions. Directing the gaze toward the ipsilateral superior direction should also be encouraged. The use of skull-shaping orthotics has recently been advocated as an additional cosmetic corrective measure although much controversy exists (93). Surgical intervention should be considered when there has been no improvement by 18 to 24 months and consists of resection of a fibrotic SCM. Successful correction can be achieved as late as 12 years old (94).

## SPINAL CORD DYSFUNCTION

There are multiple etiologies of pediatric spinal cord dysfunction including congenital such as spinal dysraphism; acquired spinal cord injury either as a result of trauma during birth or trauma after birth; vascular events, for example, a ruptured AVM; infectious/autoimmune disorders such as transverse myelitis; tumors; and disorders such as ligamentous laxity in Down syndrome or juvenile rheumatoid arthritis. The rehabilitation principles are similar for the spinal cord dysfunction secondary to these disorders in regards to bowel and bladder management, skin care, sexuality, and therapeutic intervention that will be discussed in this section. Spinal dysraphism will be the focus since it represents a significant proportion of children with spinal cord dysfunction. However, key distinctions between pediatric and adult traumatic spinal cord injury will also be discussed.

**TABLE 56.7 Differential Diagnosis of Torticollis**

Congenital postural torticollis
Intrauterine crowding

Metastatic
Osteoid osteoma/osteoblastoma
Eosinophilic granuloma
Rare primary bone/muscle tumor
Atlanto-occipital subluxations
Associated with Down's syndrome
Mucopolysaccharidoses and other conditions causing ligamentous laxity
Ocular strabismus (most commonly CN 4)
Infection
Retropharyngeal abscess
Vestibular infection (otitis media)
Cervical adenitis
Vestibular
Mastoiditis
Paroxysmal torticollis of infancy
Tumor
Midbrain tumors
Posterior fossa/intracranial tumor
Cervical cord tumor
Lymphoma
Acoustic neuroma
Orbital tumor (neurofibromatosis)
Miscellaneous
Migraine headache
Myasthenia gravis
Associated with GE reflux (Sandifer's syndrome)
Syringomyelia
Habitual, hysterical
Oculogyric crisis (phenothiazine toxicity)

### Traumatic Spinal Cord Injury

Pediatric traumatic spinal cord injury constitutes approximately 3% to 5% of all spinal cord injuries (95–97). There are several key anatomic differences between the child and the adult patient, and these predispose the child to SCIWORA (spinal cord injury without radiographic abnormalities). These differences include wedge-shaped vertebral bodies and horizontally oriented facet joints in the younger child; usually by age 8 to 10, the pediatric vertebral column resembles that of an adult. Paraspinal muscle weakness and ligamentous laxity are present as they are not fully developed in the younger patients. These factors favor ligamentous injury over bony injury (98,99). Young children also tend to have proportionally large heads compared to their body size. Therefore, the fulcrum of injury is higher resulting in higher cervical injuries than in adults (97,100) (Table 56-8). The incidence of SCIWORA varies in the literature, but SCIWORA accounts for 33% to 50% of traumatic spinal cord injury in children less than 8 years of age. SCIWORA was first termed by Pang in 1982. His follow-up article reviewing two decades of literature reported that epidemiological data suggest: (a) in the age group from birth to 9 years, there are fewer fractures and subluxations, (b) the neurologic lesion in a young child is more severe than that in an older child, and (c) because the cervical spine is inherently more unstable in the young child there are more upper cord lesions in children younger than 8 years than in older children and all of these lesions are severe (101). He also reported that the MRI findings could be used to help prognosticate outcome. Some authors/clinicians have raised the issue that term should be used only if no MRI findings are present (102), but they also indicate further discussion on this issue is warranted. SCIWORA excludes injuries from penetrating trauma, electrical shock, obstetrical complications, and those associated with congenital spinal anomalies.

It is important to be aware of the presence of SCIWORA, as in the unconscious pediatric patient in the emergency room, a lateral neck x-ray does not rule out spinal cord injury. Further diagnostic tests such as cervical MRI and CT scans may be warranted.

The management of the pediatric spinal cord injured patient is similar to the adult with a couple of exceptions. The exam of the pediatric patient is usually limited by the child's

ability to cooperate. At approximately age 5, depending on the cognitive abilities of the child, accurate manual muscle testing can be performed. It is important to remember that when assessing the pediatric patient, the resistance during manual muscle testing is not the same as exhibited by an adult. In children who cannot participate in manual muscle testing, the grading of muscle strength is an estimation. Also in the young patient, especially infants, the sensory exam should be done caudal to cranial. The child should be calmed, and then pinprick testing can be done, with the onset of a cry as the indication that sensation is present. Grading the sensory exam in infants is virtually impossible and only an estimate of the sensory level can be obtained.

There are limited data on deep venous thrombosis in the pediatric population. A retrospective review by Radecki found 1/20 patients under age 13 had a deep venous thrombosis. For the immature adolescent and child, the issue of DVT prophylaxis is not clear cut and further investigation is warranted (103).

### Spinal Dysraphism

There are several different forms of spinal dysraphism with several different terminologies used (Fig. 56-15). Spinal bifida occulta, a normal variant seen in 5% to 10% of the population, is the failure of fusion of the posterior elements of the spine with an intact thecal sac and normal spinal cord. There are usually no associated neurologic deficits although it is rarely associated with a sacral lipoma or a tethered cord. Meningocele is the failure of fusion of the posterior elements with cystic-outpouching of the thecal sac filled with CSF, but with no neural tube disruption. Therefore, there are no neurologic deficits. The skin may or may not be intact. Meningomyelocele is the significant disruption of all elements of the bony spine typically with an open malformed neural tube covered by a membranous sac. There are variable degrees of neurological deficits. Another term that may be seen is spina bifida aperta, which is any lesion that is open to the environment. Some authors also use spina bifida occulta as any lesion that is not open to the environment.

### Embryology

Normally, neural tube closure starts in the third week of gestation from the midcervical level and proceeds in both cephalad

**TABLE 56.8** Distribution by Level of Traumatic Spinal Cord Injury

Injury Type	Group 1 (0–8 Years)	Group 11 (9–16 Years)	Total
Total cervical	49 (79%)	63 (53%)	112 (62%)
Upper cervical (0-C3)	33 (53%)	31 (26%)	64 (36%)
Lower cervical (C4-7)	16 (26%)	32 (27%)	48 (26%)
Thoracic (T1-11)	7 (11%)	16 (14%)	23 (13%)
Thoracolumbar (T12-L1)	2 (3%)	17 (15%)	19 (11%)
Lumbar (L1-5)	4 (7%)	21 (18%)	25 (14%)

**FIGURE 56-15.** Major patterns of spinal dysraphism. The name of the lesion depends on the contents of the abnormal sac.

and caudad directions. The defect of neural tube closure is thought to occur around day 26 and accounts for most lesions through midlumbar. The most caudal cell mass forms between days 26 and 30 eventually resulting in formation of a central canal in the embryonic tail. Caudal regression with rostral extension resulting in fusion with the neural tube results in the formation of the spinal cord by day 53. Lesions of the lumbrosacral levels occur before day 53.

### Demographics

The incidence of neural tube defects worldwide is approximately 1 to 2/1,000 births depending on the population studied. In 2005, the U.S. rate was 18/100,000 live births and there were 734 live births with spina bifida (104). However, it is postulated there may be underreporting of this entity. Differences have been noted between races and nationalities. The populations of Irish, Scottish, or Welsh individuals have higher risks. In the United States, Hispanics have a higher risk for neural tube defects whereas the risk is lowest among African Americans (105). The incidence is decreasing worldwide and is felt to be due to several factors including better prenatal diagnosis and termination of the pregnancy, better nutritional support, and the use of folic acid and fortification of foods with folic acid (106–108).

### Prenatal Detection

Early detection can be accomplished via serum alpha-fetoprotein with levels peaking at the 16th week of gestation. False positives can be caused by incorrect dates, multiple gestations, maternal cancer, and GI or renal disease (maternal or fetal). False negatives occur with incorrect dates, intrauterine growth retardation, maternal diabetes, and Down syndrome.

Fetal ultrasound can be used to assist with diagnosis. Amniocentesis for AFP and acetylcholinesterase can be performed to confirm the diagnosis.

### Etiology

The specific etiology of neural tube defects has not been elicited. However, the mode of inheritance appears to be multifactorial with genetic and gestational influences such as folic acid deficiency and fetal exposure to valproic acid (109) or Tegretol (110). Maternal hyperthermia such as the use of hot tubs or saunas during early pregnancy has been implicated as a risk factor (111). Maternal diabetes has also been implicated as a risk factor but supportive data are lacking. The risk of recurrence has been reported in different studies to be approximately 1% to 4% after the first affected child and as high as 10% after the second. The risk of an affected mother giving birth to an affected child is 4% to 10%.

The risk of recurrence can be reduced by up to 70% with periconceptual use of folic acid in doses up to 4 mg/day. Multiple studies worldwide using 0.4 mg to 5 mg/day, given 1 month preconception through the first trimester have been performed with the majority citing a 60% to 70% reduction in risk of recurrence of neural tube defects. The Centers for Disease Control (CDC) recommends that all women of child-bearing years consume 0.4 mg/day of folic acid. Folic acid intake should be kept under 1 mg/day unless under a physician's care. Some physicians believe that higher doses such as 4 mg/day should be used if the woman has already had a child with a neural tube defect (112,113). The exact mechanism of folic acid in prevention has not yet been determined. There is an association between elevated homocysteine levels and neural tube defects. A variation (C677T) in the gene coding for 5,10-methylenetetrahydrofolate is associated with a 70% increased risk of spina bifida.

### Neural Tube Closure

Sac closure is usually performed within the first 24 to 48 hours to reduce the risk of infection. Microsurgical closure with reapproximation of the neural tube and construction of a fluid-filled pouch to “bathe” the cord had reduced the incidence of early tethering of the spinal cord.

Newer neurosurgical techniques now involve repair. Tulipan and Bruner reported three successful cases of in utero repair (114). A case study of 29 patients repaired in utero suggests that intrauterine repair of myelomeningocele decreases the incidence of hindbrain herniation and shunt-dependent hydrocephalus. However, there was an increase in prematurity (115–117). A further study strongly suggests that it reduces the incidence of shunt-dependent hydrocephalus compared to conventional treatment. It remains to be proven whether the risks of intrauterine surgery outweigh the potential benefits: five patients in one study died due to premature delivery (118).

### Associated Neurologic Abnormalities

The Chiari malformation type II, seen in 90% of patients, is defined as downward displacement of the inferior portion of the cerebellar vermis, the medulla, lower pons, and an elongated fourth ventricle through the foramen magnum. There is also an associated kinking of the medulla.

Hydrocephalus occurs in 80% to 90% of patients. A “cork in the bottle” phenomenon, related to the abnormal placement of the above-mentioned structures through the foramen magnum, aqueductal stenosis, and a defect in CSF uptake are all causative factors. More than 80% of children require ventriculoperitoneal shunting.

Symptoms of the Chiari malformation and/or hydrocephalus include laryngeal and pharyngeal paresis and may be associated with stridor and/or apnea during infancy and early childhood. Infants may be born with symptoms but typically develop them within the first 2 months with the peak mortality between 9 and 12 weeks. Mild inspiratory stridor with crying is usually the initial symptom due to paresis of the vocal cord abductors. Progressive cardiorespiratory problems including apnea and bradycardia may develop, as well as aspiration pneumonia. Approximately one third of infants develop symptoms and about one-third of these will die (119).

A tethered spinal cord may be due to a lipoma, scarring at the closure site, or diastematomyelia. Presenting symptoms include deterioration in bladder and bowel function, loss of strength or sensation, spasticity, low back pain or radicular pain and/or rapidly progressive scoliosis. It is felt that microinfarctions of the spinal cord occur with repetitive spinal flexion and extension leading to symptoms. Urodynamics may be helpful, especially since a bladder that is becoming more spastic on urodynamics, may be a symptom of a tethered cord. Treatment requires early surgical detethering. McClone reported that 93% of patients that were detethered, had improvement or stabilization of presenting symptoms (120). Spontaneous resolution of scoliosis has been reported after detethering. A tethered cord is present in almost all patients with meningocele (121) though it may be asymptomatic. Symptomatic tethered cord requiring surgical intervention occurs in about 15% to 25% of patients, but in some studies it is reported as high as 50%. Retethering can occur.

Syringomyelia is felt to be due to high CSF pressure within the central canal. Presenting symptoms include deterioration of neurologic function, loss of sensory and motor function in the upper limbs, and spasticity resulting in progressive joint deformity. It may also be present in 25% of asymptomatic patients. Shunting may be necessary when the process is symptomatic.

### Orthopedic Issues

There are associated musculoskeletal malformations and complications that can lead to further impairment. Two types of scoliosis can occur: structural and paralytic. Structural scoliosis is caused by vertebral body anomalies such as wedge or hemivertebrae, unilateral bars or block vertebrae, alone or in combination. Paralytic scoliosis is secondary to loss of truncal support and is seen in most thoracic-level patients. Kyphosis may be structural or paralytic, with higher spinal levels at greater risk for paralytic kyphosis. Rib anomalies are also seen including fused or malformed ribs. Contractures can occur at any joint due to muscular imbalance. Hip dysplasia and club feet also occur. Pathologic fractures occur below the level of

the neurologic lesion, and may be caused by trivial trauma and present as painless swelling, warmth and/or redness. There are no good data to indicate that passive standing alone reduces the risk of pathologic fractures.

Scoliosis is typically managed initially with spinal bracing for curves greater than 20 degrees and followed with regular radiographic monitoring. Curves greater than 40 degrees are considered surgical curves. Rapidly progressive scoliosis should raise the suspicion of a tethered cord. A severe kyphosis (gibbus) may be corrected by a kyphectomy. Bilateral hip dislocations without restricted range of motion may be left untreated. Unilateral hip dislocation in low-level lesions should be corrected, but in high-level lesions, surgical correction may have no benefit (122). Unilateral hip dislocation may lead to pelvic obliquity though the relationship between pelvic obliquity and scoliosis has been questioned. Serial casting or soft tissue releases to improve range of motion may be needed to increase mobility, improve positioning for seating and/or bracing.

After surgical procedures postoperative immobilization should be limited as much as possible to prevent further osteoporosis and pathologic fractures.

### Genitourinary

The majority of patients have a neurogenic bladder, with a flaccid bladder being more common than a spastic bladder. In addition, there are associated genitourinary abnormalities seen in up to 20% of patients including horseshoe kidneys, hypoplastic kidneys or renal agenesis, as well as ureteral duplications and posterior urethral valves.

A renal ultrasound should be performed early in infancy to delineate the anatomy. A voiding cystourethrogram (VCUG) can define bladder contour and determine the presence of ureteral reflux. Renal scans and urodynamics can be performed after 2 weeks of age. Since the physiology can change over the first year of life, serial ultrasounds should be performed every 3 to 4 months to monitor the status of the kidneys and detect any changes that would necessitate further intervention. Most patients will be managed with clean intermittent catheterization (CIC). The age at which this may begin is debatable. CIC may be started at birth if the child has a known neurogenic bladder. Alternatively, since infants are normally not continent, if bladder pressures are not elevated, there are no changes on ultrasound and the patient is free of urinary tract infections, then CIC can be started at the age when continence is normally achieved, perhaps 3 to 4 years old. However, once the first urinary tract infection occurs, then catheterizations must be started. The long-term goals of bladder management are to prevent renal damage by preventing infection and reflux and to prevent wetness between catheterizations. Routine renal-bladder ultrasounds should be performed every 6 to 12 months in order to properly monitor the urologic system.

Pharmacologic intervention may be needed based on the results of the urodynamics and the patient's clinical status with anticholinergic medication such as Detrol or Ditropan being used for spastic bladders.

Surgical procedures include bladder augmentation for small-capacity bladders, urethral implantation for patients with reflux, and suprapubic vesicostomy to allow for an alternative method of drainage. The Mitrofanoff procedure is used to provide an alternative conduit for urinary catheterization. The artificial sphincter is an implantable device used to help achieve urinary continence. It can be considered in a motivated patient after all other conservative methods have failed. CIC is still required. Patients should be free of infection, have normal renal function, adequate bladder capacity, and low pressure bladders with no uninhibited contractions. Problems include rejection, foreign body reaction, and infection. Neural stimulation involving stimulation of the sacral roots (123) and pudendal nerve stimulation have also been reported. Children with good fine motor skills and good cognition can be taught self-catheterization at approximately age 5. The goal is to have the child independent so their personal space is not invaded routinely. Controversial issues include the use of prophylactic medications such as antibiotics and the benefit of vitamin C.

### Bowel

The management of the bowel program in patients with meningocele is a constantly changing process. Bowel incontinence can cause terrible social stigmatization. Training in timed bowel regulation may be started by 2 to 3 years developmental age. Since peristalsis and the gastrocolic reflex are still intact, postmealtime evacuations are usually more successful. Diet is an important component of the bowel program. Adequate fluid intake is important as well as knowing which foods soften or harden the stools. Bulk additives, stimulant suppositories, and enemas may be needed. For patients with uncontrollable incontinence, the Malone antegrade continence enema (ACE) provides a surgical alternative, with a conduit using either the cecum or the appendix between the intestine and the abdominal wall. This is a catheterizable conduit that can be used to deliver tap water or saline enemas and allow for evacuation through the rectum.

### Sexuality

Sexuality does not only relate to sexual functioning but also to one's perception of self that may lead to problems of decreased self-esteem, anxiety, depression and lead to impaired social interactions. It is important to address these issues with appropriate supportive counseling when they arise.

Females may have relatively normal function in spite of sensory loss. Males have variable ability for erection and ejaculation, but fertility may be compromised by recurrent UTI, repeated mechanical trauma to the testicles, testicular hypoplasia, and decreased temperature control of the scrotum resulting in decreased sperm count.

### Skin

Patients with spina bifida are at risk for decubitus sores due to impaired mobility and impaired sensation. Meticulous skin care is important with weight shifts being done routinely by the family/caregivers and then the child when he/she gets older

and can follow through on his own. There are reports in the literature of patients requiring limb amputation due to severe decubiti. Occipital decubiti are more common in younger children that are immobile due to the large head size. Prevention is the best treatment.

### Latex

Latex allergy should be considered in every child with meningocele. Numerous different types of allergic reaction have been reported including anaphylaxis. Protein in the latex is the primary allergen. The FDA estimates that 18% to 40% of children with meningocele and 6% to 7% of surgical personnel are latex sensitive (124). Niggemann reports that atopic disposition, number of operations, and presence of a shunt all increase the risk of becoming not only sensitized but also allergic to latex. Sensitization may occur at any time, so serum IgE levels may give a false sense of security (125). Therefore, latex should be avoided in all patients with meningocele. One study from the Cologne Children's Hospital found a significant reduction in latex allergy by practicing primary prophylaxis: latex was avoided for all surgeries, anesthesia, and on the wards (126). This also indicates that repetitive exposure plays a factor in latex allergy.

### Rehabilitation

The rehabilitation program for children with meningocele begins in the newborn period. A working knowledge of normal development is important. A careful examination in the newborn period, often by observation of the position of the infant, can help discern the functional level of the patient that result from imbalance of muscular forces around major pivots. Thoracic-level lesions are most often associated with flaccid lower limbs and with frog-legged positioning. High lumbar (L1-2) levels tend to lay with hips flexed and adducted. The knees are often flexed because of intrauterine positioning. This position predisposes to early hip dislocation. Children with low lumbar (L3-5) levels lay with the hips flexed and adducted but with the knees in extension and possibly the ankles dorsiflexed. Hip dislocation may be a late complication. Individuals with sacral levels may assume normal postures, but pes cavus and clawing of the toes may be seen.

Children develop psychosocially by interacting with their environment. If motor limitations exist, adaptive devices will be needed to help facilitate this interaction. Adaptive equipment in infancy is designed to allow attainment of functional milestones at as near to normal time as possible. Proper seating with appropriate relief for deformities allows the infant to sit upright and view the environment. At about 1 year of age, standing devices can be considered. The data are limited in regards to passive standing alone and the prevention of osteoporosis. The devices used include a stander or parapodium for thoracic-level patients, although the parapodium is typically not used for mobility until at least 18 months of age. For thoracic-level patients, the parapodium can be replaced by HKAFs with the use of a walker or Lofstrand crutches, depending on the child's abilities. Ambulation in childhood,

even in high-level patients, is a reasonable goal, although by adolescence, wheelchair ambulation may be required as a result of the energy demands of upright ambulation. The reciprocating gait orthosis (RGO) allows for an upright energy-efficient gait pattern. The isocentric RGO is the newest version, using a bar with a central pivot (Fig. 56-16). The quality of gait is improved if the patient can assist with active hip flexion. The energy consumption of ambulation with RGO approaches that of wheelchair mobility. In the study by Cuddeford and associates, energy consumption and energy efficiency of HKAFOs and RGO were compared. Previous studies had shown less energy consumption with RGO than with a swing-through gait with HKAFOs. The children who ambulated with HKAFOs had significantly higher energy consumption than those with RGO, but they ambulated faster. Therefore, the energy efficiency was less for the HKAFO group. The authors believe

**FIGURE 56-16.** Isocentric RGO for spinal dysfunction.

that further investigation is needed to confirm the importance of energy efficiency during ambulation in considering a mode of locomotion with the child with meningocele (127). High-lumbar-level patients may receive bracing as early as 10 to 12 months, usually with HKAFOs. For lower-level patients, the residual motor movements will dictate the type of orthotic needed. Wheelchair ambulation can be achieved by 18 to 24 months, and steering a power wheelchair can be achieved before 3 years of age.

There are multiple factors that affect ambulation, including level of paralysis, age when first braced (128) obesity, degree of scoliosis, lower-extremity deformities, weight and efficiency of the orthosis, child's motivation, parental support, cognition, and upper-extremity function. If a child with meningocele wants to ambulate, she should be given every opportunity to ambulate. Carney and Melchionni, in a retrospective study, evaluated high-lumbar and thoracic-level patients and found that the significant factors determining ambulation were degree of mental retardation, whether the child received physical therapy for ambulation, and parental involvement (129). Typically, most sacral-level patients will ambulate as adults, and most thoracic-level patients will require wheelchair mobility.

A high proportion of these children will have learning disabilities, and the appropriate supports need to be provided in the school setting. Supportive counseling may be needed to help the child cope and effectively manage his/her disability.

### Prognosis

There are several studies regarding follow-up of patients with meningocele.

Worley and associates monitored 63 patients (32 boys and 31 girls) for 5 years from infancy. Ninety-eight percent had VP shunts and 23% had symptoms of brainstem dysfunction, with the median age of 3 months (1 to 22 months). Eleven of fifteen underwent brainstem decompression. In four of fifteen, symptoms resolved spontaneously. Mortality rate at 5 years was 14%; five of nine died as a result of brainstem dysfunction (130). Hunt and Poulton reported a 25-year follow-up of 117 patients born between 1963 and 1970. Fifty-two percent, or 61 patients, were alive in 1992. Seventy-nine percent lived to their first birthday, 63% to their tenth birthday, and 56% to their twentieth birthday. The most severely disabled patients had the highest mortality. Sixteen deaths were due to renal failure. CIC was not a standard of care when many of these patients were younger, however. Of the 61 survivors, only 33 were able to live independently (131).

### A Team Approach

The rehabilitation of the child with spinal cord dysfunction is multifaceted and requires a team approach. The physiatrist can guide the team, which may include an orthopedic surgeon, neurosurgeon, urologist, psychologist, social worker, physical therapist, occupational therapist, speech therapist, and nutritionist. Finally, it is important to include not only the child as part of the team, but the parents as well. Parents must be involved for a successful rehabilitation program.
